
The Seward Identikit...

Every stainless steel Lloyd-Davies' Sigmoidoscope made by Seward has components which are absolutely identical – guaranteed interchangeable.

And that's an immense advantage when a lot of these instruments pass through the CSSD together. Because you never need to label any parts, or worry about 'matching up'.

Which saves time. Cuts losses.

You'll probably agree, the Seward Lloyd-Davies' Sigmoidoscope* is good news.

Well, here's some more.

The Seward St. Mark's Proctoscope*.

Made entirely of stainless steel. With all parts absolutely identical – guaranteed interchangeable.

**Electric and non-electric models available – leaflets on request*

seward –the fast word in quality

SURGERY MICROSCOPE II

Another superb instrument from

CARL ZEISS
JENA

This well established Surgery Microscope from VEB Carl Zeiss Jena has gained a well deserved reputation for it's reliability and all-round performance. It is extremely versatile, allowing complete freedom of movement. The working distance is 200-300 or 400mm. You'll be surprised at the competitive price of this popular microscope which incorporates optics of the highest quality. Remarkable value!

SPECIAL FEATURES INCLUDE:-

- ✻ Individually focussing eyepieces
- ✻ Rapid changing for two filters and five magnifications (5x, 8x, 12.5x, 20x, 32x)
- ✻ Observer eyepiece available
- ✻ Photographic attachments available.

Write or telephone for literature or demonstration on this instrument and others in the comprehensive VEB Carl Zeiss Jena Range.

CARL ZEISS JENA LTD., C.Z. Scientific Instruments Ltd.,
P.O. Box 43, 2 Elstree Way, Borehamwood, Herts WD6 1NH. *Tel: 01-953 1688.*
Manufactured by: VEB Carl Zeiss Jena, Carl Zeiss Strasse 1, Jena, GDR.

EDITORIAL NOTICES

Original articles or reviews are invited and editorial communications should be addressed to the *Editorial Secretary, British Journal of Surgery, c/o John Wright & Sons Ltd., Bristol BS8 1EX.* Articles are accepted on the understanding that they are contributed to this Journal only, and that articles and their illustrations become the property of the Journal unless the authors state, before publication, that they reserve the right to themselves. Each article should be accompanied by an adequate summary, suitable for publication. Authors are asked to ensure that original illustrations are securely packed and adequately protected.

BUSINESS COMMUNICATIONS should be addressed to *John Wright & Sons Ltd., British Journal of Surgery, Bristol BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery.*

BINDING.—Handsome Cloth Cases may be obtained for binding Vol. 60. Case, £2·00 post free; Case and binding, £7·50 post free. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers, who will also undertake the binding if desired.

ADVERTISMENTS.—All communications should be addressed to *Hexagon Publishing Co. Ltd., 10 Spencer Street, St Albans, Herts AL3 5EG* (telephone St Albans 60641).

Instructions to Authors

PREPARATION OF MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

ILLUSTRATIONS AND TABLES

Illustrations should be clearly marked on their backs to show number, orientation and author's name. Explanatory legends should be typed on a separate sheet of paper accompanying the manuscript. For halftones, glossy photographs or positive prints (*not* X-ray negatives or slides) should be sent, unmounted wherever possible. When coloured illustrations are submitted as colour prints, they should be accompanied by the original transparencies where possible. As colour illustrations are expensive to reproduce, authors may be asked to make a contribution towards the cost. Drawings should be in a finished state suitable for reproduction. Any lettering should be large enough to withstand a reduction in size; sans serif lettering is recommended.

Tables should be typed on separate sheets of paper accompanying the manuscript. They should have an identifying number and a short descriptive heading. *All illustrations and tables must be referred to in the text.*

REFERENCES

The citation of references should follow the pattern shown in the Reference Citation Recommendations issued by the Medical Section of the Library Association. Copies of these recommendations can be obtained from the Secretary, Medical Section, The Library Association, 7 Ridgmount Street, London WC1E 7AE.

The name of the author and the date of publication are given in the text; the list of works cited is put at the end of the article, arranged in alphabetical order of authors' names. When references to two or more works by the same author are listed, they are arranged in chronological order. Where there are two or more authors (apart from the main author), these may be indicated in the text citation by the words 'et al.', following the name of the principal author; on the rare occasions when this may lead to confusion, the text citation should name as many of the collaborating authors as are necessary to identify the work cited. When several works published by the same author(s) in the same year are cited, they should be distinguished by the letters a, b, c, etc., placed immediately after the date.

In the list of works cited each reference to a *journal article* should give, in the order indicated, the names and initials of all authors, the year of publication (in parentheses), the title of the paper, the name of the journal (abbreviated), the volume number (in heavy type arabic numerals) and the numbers of the first and last pages of the article. Abbreviations for journal titles should be those adopted by *Index Medicus* since January 1971; where no abbreviation is given by *Index Medicus* the journal title should be left in full and the publishers will provide a suitable abbreviation. A reference to a *book* should give, in order, the names and initials of all authors, compilers or editors, the date of publication (in parentheses), the title of the book, the edition number (if other than first), the place of publication, the publisher's name and, where appropriate, the number(s) of the page(s) referred to. A reference to a *contribution to a book* should give, in order, the names and initials of all authors of the contribution, the date of publication (in parentheses) and the title

of the contribution; then, after the word 'In:', there should follow the name(s) and initial(s) of the author(s) etc. of the book, the title of the book, the edition number (if other than first), the place of publication, the publisher's name and the numbers of the first and last pages of the contribution.

Titles of papers and books should be given in the original language, with titles in Cyrillic and Greek alphabets transliterated

Only in papers in which many and frequent references have to be made should the items be numbered; the numbers may then be inserted in the text without interrupting it with a list of names and dates.

Proceedings of a conference held in Coventry at which leading thoracic surgeons from all parts of the world discussed recent advances in oesophageal surgery.

SURGICAL DEPARTMENTS IN HOSPITALS– The Surgeon's View

Ed.by: **PROFESSOR SIR DONALD M. DOUGLAS, MBE, MB, ChM, MS (Minn), FRCS, FRCS (Ed).** *Professor of Surgery, University of Dundee, President of the Royal College of Surgeons of Edinburgh.*

144pp. Ill. £2.50 0 407 40340 X

The findings of a Study Group set up in 1967 to report on the planning and organization of surgical departments in hospitals. This makes absorbing reading for all surgeons, theatre nurses and hospital administrators, and is invaluable to hospital specialists engaged in planning new departments.

A SYSTEM OF ORTHOPAEDICS AND FRACTURES–4th Edition

By: **A. GRAHAM APLEY, MB, BS, FRCS.**
Consultant Orthopaedic Surgeon, Rowley Bristow Orthopaedic Hospital, Pyrford, Surrey; Consultant in Administrative Charge of the Accident and Emergency Centre, St.Peter's Hospital, Chertsey, Surrey.

284 pp. Ill. £7.50 0 407 30705 2

This book is a must for the postgraduate student reflecting, as it does, the important changes in the subject during the past few years and with the text and illustrations extensively updated. For surgeons and all those engaged in the care and management of orthopaedic and fracture patients this is an essential book.

THE UPPER CERVICAL SPINE
Regional Anatomy, Pathology and Traumatology
A Systematic Radiological Atlas and Text Book

By: **DETLEF VON TORKLUS,** *Senior Lecturer in Orthopaedic Surgery, University of Hamburg; Director, Orthopaedic Clinic and Outpatient Department, University Hospital, Hamburg, and*

WALTER GEHLE, *Lecturer and Clinical Tutor in Orthopaedic Surgery, University of Hamburg; Senior Staff Physician, Orthopaedic Clinic and Outpatient Department, University Hospital, Hamburg.*

English Translation by L.S. Michaelis, MD.

112 pp. Ill. £7.00 0 407 91001 8

A thorough account of the anatomy and pathology of the upper cervical spine with comment on related clinical symptoms. The authors' original findings will be of considerable interest to radiologists, orthopaedic surgeons and physicians, neurologists and neurosurgeons.

WESTMINSTER HOSPITAL SYMPOSIUM ON CHRONIC DUODENAL ULCER

Ed.by: **CHRISTOPHER WASTELL, MS, FRCS.** *Senior Lecturer in Surgery, Westminster Hospital Medical School; Honorary Consultant Surgeon, Westminster Hospital, London.*

283 pp. Ill. £5.00 0 407 10001 6

The proceedings of the Symposium held at Westminster Hospital Medical School on 24th–25th May, 1973, which attracted an important team of speakers, each well known for his specific subject.

POSTGRADUATE SURGERY LECTURES 2

Ed.by: **JOHN McFARLAND, MD, ChM, FRCS.**
1974. 132 pp. Ill. £2.65. 0 407 10006 7.

This second volume in the Postgraduate Surgery Lectures series presents selected lectures from the 1972–73 season at the Liverpool Medical Institution.

in 86 (somewhat less than one-third). Any procedure that can combine removal of the growth with conservation of functioning lung tissue is preferable. It is repellent to excise a quantity of healthy lung that could with advantage have been left.

On the other hand, by being too conservative surgeons can endanger the chance of their patient being cured. The first aim with this dreadful disease should be to cure the patient. It is long survival that counts, especially in the many patients aged 40 or 50 presenting with this disease. A weak policy of conservatism routinely is surely not in the best interests of the patient. Cancer of the lung is not a standard disease and the type of operation to be done should be decided by a survey of each individual problem.

For example, an elderly patient with a well-localized tumour within a lobe can be treated by lobectomy. When respiratory function is impaired it becomes important to conserve lung tissue at any age. However, for a man of less than 50 years of age the chance of a lasting cure and of longevity is paramount and in general this demands a more radical operation. This is in keeping with our knowledge of cancer anywhere in the body. When some form of biological control becomes possible no doubt we shall be able to profit by planning less radical types of operation for cancer. At present a subradical course of treatment with radiotherapy can be a valuable preliminary to operation, as has been shown by results with and without this adjuvant. So far cytotoxic drug therapy has not been helpful.

Pneumonectomy, as ordinarily practised, might well be thought a radical procedure in itself. Indeed it may be a fully radical procedure, but it cannot be so in all cases. The classic cancer operations demand removal of the affected viscus together with its fascial connections and as much of the associated lymphatic field as possible. A more radical operation will include removal of the anterior and posterior mediastinal fatty tissue and lymph nodes, and clearance of the right or left tracheobronchial group of nodes and also most of the inferior tracheobronchial group. It is also important to secure as a routine the vessels within the pericardium and to excise an area of pericardium around the main vessels in order to avoid disturbing the hilar structures, especially the lymphatics. Details of the radical operation are available in the original description of the operation (Brock and Whytehead, 1955).

This more radical operation does not carry a higher mortality as the results will show. A radical procedure permits removal of the lung in a higher proportion of cases and thus the range of operability is increased. Although this inevitably embraces more poor risk subjects the mortality is still not adversely affected.

Results

Lobectomy

Table I shows the results of lobectomy in 86 cases. *Table II* shows the long term survival after operation. It will be seen that 2 patients survived for more than 20 years; one is still alive after 29 years and had a second lobectomy (contralateral) 13 years ago. Thus 34 patients lived 5 years or more; that is 40 per cent of those who had an operation and 41 per cent of those who survived operation.

Simple pneumonectomy

Table III shows the figures for this operation. *Table IV* shows the long term survival after operation. It will be seen that 8 patients survived for over 20 years and 2 for over 30 years. Both the latter patients are still alive at 30 and 34 years. Thus 21 patients lived

Fatal cardiac tamponade and other mechanical complications of central venous catheters

T. E. B. DANE AND E. G. KING*

SUMMARY

A fatal cardiac tamponade caused by an intact polyethylene central venous catheter perforating the wall of the right ventricle is reported. A retrospective review of 105 central venous catheters used in an intensive care unit revealed a high incidence of catheter malposition and a 20 per cent mechanical complication rate. The possible causes of these malpositions and complications are discussed. Guidelines for the safer use of central venous catheters are presented.

A POLYETHYLENE central venous catheter caused fatal cardiac tamponade by perforating the right ventricular wall of a 70-year-old man. This accident prompted a retrospective review of catheter location and mechanical complications in a series of 105 central venous catheters. The findings from this review have been used to formulate guidelines for the safer use of these catheters.

Case report

A 70-year-old white male required intensive care following surgery for a complicated strangulated inguinal hernia. His problems included hypovolaemia, abdominal sepsis, oliguria and hypoxaemic respiratory failure. A 95-cm polyethylene catheter (Argyle Medicut) was inserted in his left antecubital fossa by surgical cutdown on the basilic vein. Its position in the superior vena cava with the tip entering the right antrium was confirmed radiologically. This catheter was used to monitor central venous pressure, to draw venous blood samples and to infuse intravenous fluids.

The patient's condition improved initially, but he needed a repeat laparotomy to repair a leak from the bowel anastomosis, tracheostomy for prolonged ventilatory support and haemodialysis for acute renal failure. On the twelfth day in hospital a similar polyethylene catheter was inserted in his right antecubital fossa by surgical cutdown on the basilic vein. It was also shown radiologically to be located in the superior vena cava with its tip entering the right atrium. This catheter was used without incident for 24 days to infuse casein protein hydrolysate (C.P.H., Cutter Laboratories), 50 per cent dextrose solution and fat emulsion (Intralipid 10 per cent, Pharmacia) with an infusion pump at a total volume of 120 ml/hour.

At 16.30 hours on day 36 the catheter in the patient's right arm began to leak from a crack in the exposed portion and was replaced by a similar catheter inserted at the same site. Radiological location of the new catheter showed it to be too far advanced and coiled in the right atrium and superior vena cava (*Fig.* 1). The catheter was withdrawn 12·5 cm but a repeat X-ray to confirm its position was not done. Infusion of the intravenous feeding solutions was continued as before and the patient remained well until 16.00 hours on day 38. He then became restless and nauseated, a nasogastric tube was inserted and he remained well until 18.00 hours that day, when he again became restless and nauseated. His vital signs remained stable throughout this period. Fifteen minutes later, while being examined to determine the cause for his restlessness, he developed a bradycardia of 40/minute, lost consciousness and had no recordable blood pressure. Cardiopulmonary resuscitation was started immediately but the bradycardia progressed to asystole which was unresponsive to all attempts to reverse it. While attempting to insert a transthoracic pacing electrode 15 minutes after starting resuscitation, a white liquid was aspirated from the region of the heart. Approximately 100 ml of this white material were removed but resuscitation was still unsuccessful. The central venous catheters were left *in situ* until post-mortem examination was carried out.

At post-mortem the anterior mediastinum and left pleural space contained a small amount of the white liquid and 80 ml were aspirated from the pericardial sac. This liquid was macroscopically similar to the intravenous feeding mixture being infused prior to the patient's death. When the pericardium was opened, the tip of a polyethylene catheter was found to be protruding 1 cm from the anterior surface of the right ventricle. There was an area of bruising, approximately 2 cm in diameter, on the surface of the myocardium around the catheter exit site (*Fig.* 2). Opening the heart revealed that the catheter from the left arm ended in the right atrium, but the other, from the right arm, crossed the tricuspid valve and perforated the anterior wall of the right ventricle (*Fig.* 3).

Review of central venous catheter locations and complications

The records and X-rays of all patients admitted to an 8-bed surgical intensive care unit over a 6-month period were reviewed retrospectively.

During the period under study, central venous catheters were inserted when one or more of the following indications were fulfilled:

1. To monitor central venous pressure when this was considered a desirable aid in management.
2. To withdraw venous blood samples when frequent laboratory estimations were necessary.
3. To infuse intravenous fluids and drugs over a prolonged period when peripheral veins were scarce or difficult to cannulate.
4. To infuse hypertonic intravenous feeding solutions.

The central venous catheters were inserted by rotating residents and medical students under supervision of the residents. The insertion site of first choice was the basilic vein in either antecubital fossa, but when these sites were not available the cephalic vein in the deltopectoral groove or the external jugular vein was occasionally used. A standard 95-cm polyethylene catheter, of external diameter 2·08 mm, with a radio-opaque marker line (Argyle Medicut sentinel line catheter), was inserted by surgical cutdown. Catheters were not sharpened and were inserted until free aspiration of blood and easy flow of the intravenous solution suggested that the tip was located in a central vein. The catheter was then

policy and practice is to assume that deep irradiation can confer extra therapeutic benefits and that certain patients should have the additional help that irradiation offers.

In young patients (under 35 years of age) the operation is not performed without some preoperative radiotherapy. Similarly, in all patients under the age of 45 and in many under the age of 55 preoperative radiotherapy is advised because of the fear that the handling at operation of a lung growth in patients of this age may favour dissemination.

In closing a discussion on preoperative irradiation Shields (Shields et al., 1970) said that he felt like an unappreciated St George, for he had hoped to kill the dragon of the routine use of deep X-ray therapy. He claimed that his results showed that though you can operate upon more patients following preoperative irradiation, you do not save any more than without it.

The present author's experience with radiotherapy *after* operation has been generally disappointing. If an inoperable growth is disclosed there may be a good case for radiotherapy but its value is uncertain, and in the author's experience no case found to be inoperable at thoracotomy became operable after postoperative irradiation.

The development of a new lung cancer

It is desirable to consider the development of a new lung cancer in patients who have been cured of one cancer of the lung. Clearly this very interesting biological occurrence could not be observed until successful operation had provided prolonged survival. It is remarkable that lung cancer caused or activated by an external irritant does not frequently occur in more than one site. Nature can be prodigal in her gifts and bilateral lung cancer now has a considerable literature devoted to it.

Hughes and Blades (1961) recorded 2 cases of a second lung cancer occurring 9 and 10 years respectively after resection of the original primary. Le Gal and Bauer (1961) surveyed the literature and recorded 4 cases of a second lung cancer in 63 patients who had survived for 30 months or more after resection of their first growth. Watson (1965), in a study of 10-year survival in lung cancer, considered a group of 2540 cases suitable for a 10-year study and found 56 survivors. A second lung cancer developed in 4 of these 10-year survivors.

In the present series of 293 patients 2 had a bilateral growth for which simultaneous resection was done but without success. Nine other patients developed a *new primary growth* or what appeared to be one.

In 1 patient who had a right lower lobectomy in 1945 for a squamous-celled carcinoma, a new primary squamous-celled growth appeared in the left upper lobe in 1961, that is 16 years later, and this was successfully removed with conservation of the lingula, and he remains well 13 years later. In addition to these 9 cases a tenth patient who had a pneumonectomy done by an assistant in 1953 developed a new primary in his right lower lobe 10 years later. This patient had continued to smoke 20 cigarettes a day since his first operation, and the patient mentioned above whose new cancer was successfully resected had also continued to smoke after his first operation. A smoking history was not obtained in all the other patients, but at least 5 had not abandoned smoking. It is clear that a man or woman who has had a cancer of the lung successfully treated must be told that he must NOT smoke again.

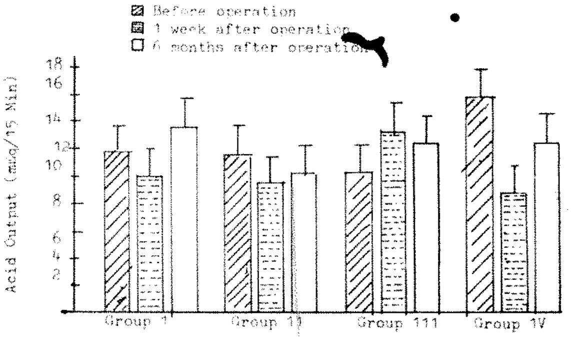
▼ ORIGINAL REDUCED TO REQUIRED SIZE



The above type of illustration conveys information, but the author probably did not expect it to be reproduced without redrawing. The typewritten annotations are not acceptable. The figures are not properly placed with respect to the scale, the use of the Arabic numeral 1 for Roman numerals along the bottom axis is incorrect, and of course the entire drawing is too rough to be acceptable in a journal. In the redrawn version all of these points have been taken care of, and the three columns have been more clearly differentiated by the use of black, white and a stipple of sufficient size to reproduce satisfactorily at the reduced scale.

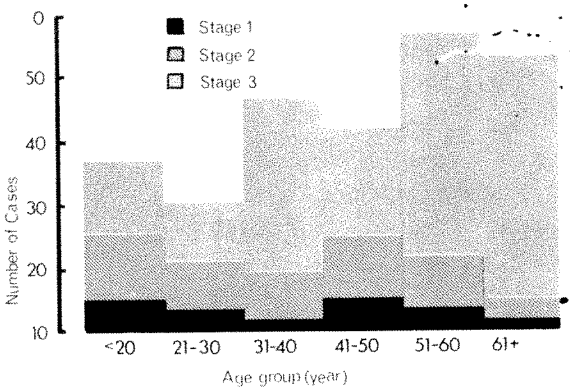
▼ ORIGINAL REDUCED TO REQUIRED SIZE



At first sight the artwork, of which a portion is reproduced at the same scale above, appears to have been quite carefully produced. Clear lettering has been applied, probably by Letraset, and two different tints have been used, probably from the same source. However, a reduction to the size necessary for printing in the Journal reveals the fact that the stipple used for stage three was too fine to give a smooth reproduction at a smaller scale. The problem which arises when two tints of this kind meet is also shown.

In most places an even white margin has been achieved, but where even the slightest overlap has been allowed to occur an unpleasant interference pattern develops, as between the 51–60 column and the 61+ column. The heading Age group (year) shows the difficulty of maintaining accurate alignment of the type of lettering used. In the redrawn versions, shown below, the section of the full scale reproduction shows how much larger the stipple needs to be in order to reproduce satisfactorily at a reduced scale. The lettering has been typeset in accordance with the typographical style of the Journal, and pasted on to the artwork. It will also be seen how much clearer this type of diagram is when the columns are outlined.

Artwork for The British Journal of Surgery

NOTES FOR THE GUIDANCE OF ILLUSTRATORS

The Editorial Board of the *British Journal of Surgery* are very anxious to improve the standard of the illustrations used in articles published in the Journal. In general, they feel that little criticism can be directed at the photographs supplied by authors, but that frequently line illustrations, charts and graphs have in the past appeared in an unsatisfactory form. The attention of authors is therefore drawn to the brief notes on this subject given under the heading 'Instructions to Authors' under Editorial Notices among the preliminary pages of each issue of the Journal.

The following additional notes have been prepared for the guidance of authors and their artists, but it is intended in future to subject artwork submitted to a somewhat more critical examination than heretofore, and in cases where the artwork is found to be unsuitable for reproduction, to refer it back to authors for improvement. At the same time, the publishers are able to offer a service for the re-lettering, the improvement or the total redrawing of artwork at a moderate cost if this should prove more convenient to authors than recommissioning the work themselves. The cost of redrawing a simple block diagram with some lettering could be of the order of £4, while a highly detailed anatomical drawing could involve a charge of £15 at mid-1974 costs.

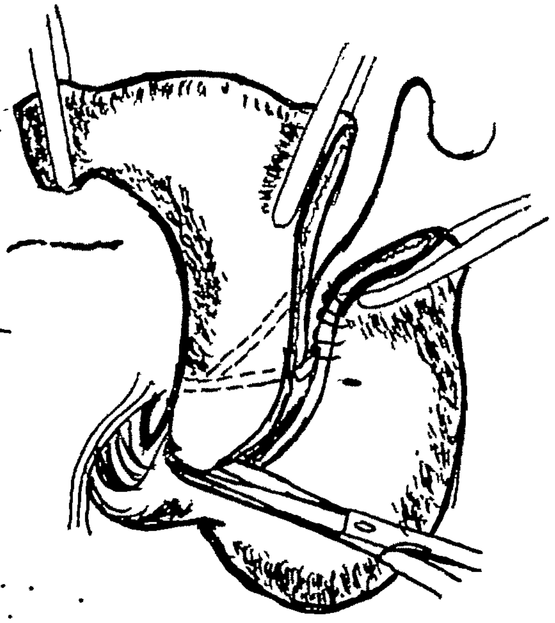
It should be borne in mind that an artist will normally draw a diagram at a considerably larger scale than would be appropriate for reproduction in the pages of a journal, where space is at a premium. The artist must consequently bear in mind that when his drawing is photographically reduced in size the thickness of every line and the size of all lettering will be proportionately reduced; unless due allowance for this subsequent process is made at the drawing stage the end result may well have lines and symbols that are so light in weight as to be scarcely visible and lettering so small and crowded as not to be easily legible.

Since the Journal has been re-styled it will be noted that whenever possible line diagrams are reproduced at column width, i.e. 74 mm. Sometimes it may be necessary to use the full page width of 152 mm and, rarely, an intermediate width can be accommodated. The ideal line width for the main axes of graphs or charts as printed is approximately $\frac{1}{2}$ mm, about $\frac{1}{8}$ mm or $\frac{1}{4}$ mm being regarded as the lightest line weight that should normally be used for detail.

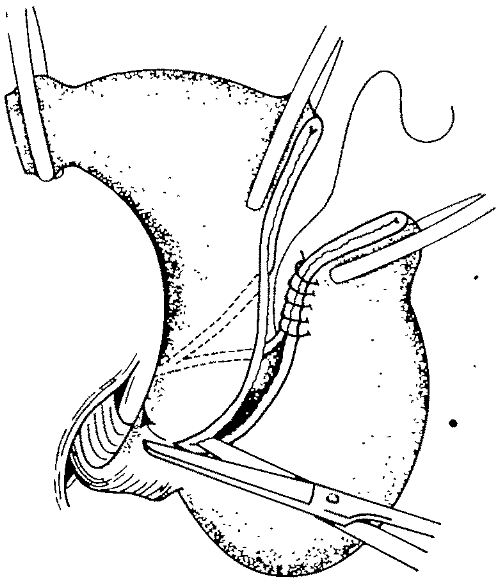
Another problem frequently arises with shading, or with various types of cross-hatching used, for example, in histograms. In these cases it is quite common for the artist to space the shading lines in such a way as to look most satisfactory on the original artwork, but on reduction in size the lines are seen to merge together and so produce an unsightly and irregular effect. Relatively open shading should always be used.

Lettering—as already mentioned in the Instructions for Authors—should be in sans serif style, and it should be drawn at such a size as to reproduce no smaller than 3 mm. from the top of the capital letter to the bottom of a descending letter, such as y. General titles, descriptive headings and units along the axes of graphs should be slightly larger.

▼ ORIGINAL ILLUSTRATION RECEIVED FROM AUTHOR



▼ REDRAWN VERSION OF ILLUSTRATION



This reproduction of the type of drawing sometimes received contrasts with the professionally redrawn version alongside. From many points of view the rough detail in the original version would have looked better at a reduced scale, but in fact the effect of reduction would have been to clog up much of the detail, and produce an even rougher appearance.

5 years or more; that is 24 per cent of those who had an operation and 30 per cent of those who survived operation.

Radical pneumonectomy

Table V shows the figures for this operation. *Table VI* shows the long term survival after operation. Thirty-nine patients lived 5 years or more; that is 33 per cent of those who had an operation and 39 per cent of those who survived operation.

Comparative results

These are presented in *Table VII*. One patient had bilateral lobectomy with an interval of 16 years and 2 patients had simultaneous bilateral lobectomy and segmental resection and lobectomy respectively.

The 5-year survival is based on the number of patients surviving operation and not on those originally submitted to operation.

It is common to find the 5-year survival rate after lobectomy to be high, e.g. 40–50 per cent, but this is in essentially a selected group. In the present series it was 41 per cent. A search of the world literature failed to find a 5-year survival rate after pneumonectomy of over 33 per cent. The 5-year survival rate after radical pneumonectomy of 39 per cent in the present series is significant. This is almost the same as the survival rate after lobectomy (41 per cent) and it suggests that radical pneumonectomy does improve the chance of 5-year survival.

Irrespective of the type of operation, it is noteworthy that in patients in whom removal of the growth is possible there is a 1 in 3 chance of 5-year survival. This can be comforting and encouraging knowledge to give to a patient or his relatives.

The object of the radical operation is to try to catch in the wider surgical net lymph nodes that are involved by the growth and which would otherwise not be removed. Some indication of what is achieved is given in *Table VIII*. The diminished survival rate when nodes are invaded is clearly shown and corresponds with all published experiences. On the other hand, 9 patients in whom invaded nodes were removed lived for more than 5 years after operation. Without a radical operation they could scarcely have survived for so long. Some of these patients have survived for much longer than 5 years after removal of invaded lymph nodes, as is shown in *Table IX*. Six survived for more than 10 years and 3 are still alive 13, 16 and 24 years respectively after operation.

Nine patients in whom the nodes were not involved at operation are still alive after 25, 23, 22, 20, 15, 15, 15, 9 and 8 years respectively.

After this separate presentation of the results of three different types of resection it is desirable to present the combined figures of long term survival. These are shown in *Table X*.

Table VIII: SIGNIFICANCE OF NODAL REMOVAL BY RADICAL PNEUMONECTOMY

Comments on long term survival

As malignant disease commonly occurs in middle-aged or elderly people it is clear that in a long follow-up deaths may occur from causes unconnected with the malignant disease itself. Thus age alone may be the cause. The earliest long-surviving patient in this series was aged 49 when he was operated on in 1939. His death nearly 26 years later at the age of 75 was, therefore, not unusual. Similarly, a man aged 63 who had a lobectomy in 1941 came to a natural end 21 years later at the age of 84. These are only two examples of many similar cases. In 1940 a man aged 43 underwent pneumonectomy and is now, 34 years later, 76 years old and the longest survivor in this series. His natural expectation of life must inevitably be short.

In a large series such as this with patients coming from many countries of the world some are inevitably lost to follow-up. This has been so in 11 cases and death has been assumed at the date of the last information. On the other hand, persistent search has often brought unexpected news of a good result. Thus a woman operated on at the age of 31 in 1943 was lost to follow-up in 1963 but was found to be still alive and well in 1973, 30 years after the operation.

Two unusual cases merit special mention. A man aged 52 underwent right lower lobectomy for a squamous-celled carcinoma in 1945; in 1961 at the age of 67 he developed a new carcinoma of the left upper lobe for which a lobectomy was done. He is still alive and well 13 years later at the age of 81! In 1949 a woman aged 27 presented with a hopelessly inoperable carcinoma of the right main bronchus with extensive carinal node involvement. She was treated with deep irradiation and some 6 months later was able to undergo a radical pneumonectomy. She is still alive 24 years later.

These 2 cases, and certain others, impress one with the importance of a biological factor being present

Table XI: HISTOLOGICAL TYPE OF THE TUMOUR IN 272 CASES

Type	No. of cases
Oat-celled	46
Anaplastic or undifferentiated	35

Adenocarcinoma	36
Columnar-celled	11
Transitional-celled	5

that determines cure or early recurrence and death. As a surgeon one excusably takes some credit for long freedom from recurrence and even apparent cure (as for example when 34 years have passed since operation), but in spite of this we should be wrong to attribute all our success to our surgery when it is more probable that some favourable biological factor has been present and responsible. Conversely, in cases in which operation has been done early and apparently efficiently and yet recurrence kills the patient in a few months, an adverse or unfavourable biological determining factor may well be present. It would be wrong in the one case to assign very great credit to surgery, just as in the other case it would be wrong to attribute all the failure to surgery. Some other deeper process is involved, although as yet imperfectly understood. Advance in the treatment of cancer of all types must wait until we understand more fully the biological factors involved and how we can control them. Operation alone can never achieve this and, indeed, few surgeons would disagree that the time will come when cancer can be controlled by some process, doubtless biological, that enables us to dispense with the unpleasant, often mutilating and uncertain operations that we now must do, just as the advent of antibiotics has seen the revolution in the management of infective processes.

One well-recognized and frequently documented factor involved in the varying prognosis in lung cancer is the histological type of the tumour; that is, the cellular composition. This seems to involve a biological factor of great importance. A few simple conclusions emerge from a consideration of the histological nature of the growths in this series.

Three examples of sarcoma occurred. No histology is available in 18 cases. Of the remaining 272 cases, the histology is shown in *Table XI.*

The allocation to one specific type often varies with the individual histologist. The groups of 'anaplastic' or 'undifferentiated' carcinoma are especially uncertain and only a general assignment is possible.

In great contrast to the squamous-celled are the oat-celled and anaplastic or small-celled growths. Of patients with the former, 42 survived operation for an average of 3 years; of those with the latter, 30 survived operation for an average of just over 3 years.

The author has never been impressed with the conclusions published in the Medical Research Council's report in 1966. This had the objections of far too numerous participants (50 surgeons) over too short a time (2 years). Their essential recommendations were that operation offered very little in the oat-celled and small-celled types of growth and that slightly better results could be achieved by radiotherapy. Many thoracic surgeons have had similar experiences to the author with this type of growth, namely that although in general the prognosis is poor, long survival can sometimes be achieved.

One of the early patients in this series, operated on in 1939, had an oat-celled carcinoma and he lived for over 25 years until the age of 75. Of the 73 patients with an oat-celled or small-celled carcinoma who survived operation, 8 lived for between 5 and 10 years, 7 more than 10 years and 2 over 20 years (24 and 25 years respectively). From this experience it would be wrong to reject operation in the treatment of all oat-celled or small-celled growths.

Favourable biological factors have been mentioned in general terms, but there are other factors that appear to be more favourable.

Empyema and long survival

The patient with an oat-celled cancer who lived for more than 25 years developed an empyema after his pneumonectomy, and it has been suggested by several authors and most recently by Ruckdeschel et al. (1972) that the development of a pleural infection may be favourable to long survival by enhancing the body's natural resistance to the cancer; just as was suggested in the case of sarcoma by Coley. Two other patients in the present series who were operated on in 1940 also developed an empyema. One lived for 27 years and then died of a new cancer in the remaining lung; the other patient is still alive 34 years later. It is noteworthy that Graham's first successful pneumonectomy patient developed a pleural infection and survived 30 years (Graham and Singer, 1933).

The occurrence of an empyema after pneumonectomy can be a serious event and may result in early death rather than prolonged survival.

In the whole series of 293 cases a postoperative empyema occurred in 27 patients (3 who had a lobectomy and 24 who had a pneumonectomy).

Of the 24 patients who had an empyema after pneumonectomy, 12 lived for more than 5 years, that is 44·4 per cent. This is definitely higher than the 5-year survival rate for simple pneumonectomy which is 30 per cent in this series. Eleven patients lived for more than 10 years (40·74 per cent) and 4 for over 20 years (20 per cent).

From these figures it would appear that the occurrence of a pleural infection may be favourable to long survival probably because of some immunological factor.

Radiotherapy

The best treatment for a lung cancer is to excise it. Radiotherapy alone can rarely cure a patient and is disappointing in the prolongation of life that it confers. There is good evidence from many authors that it can convert an inoperable cancer into one that can be removed, as in the case cited earlier. A question that we must ask is whether preoperative irradiation can increase the chance of cure or of long survival when the growth appears to be operable. The author's

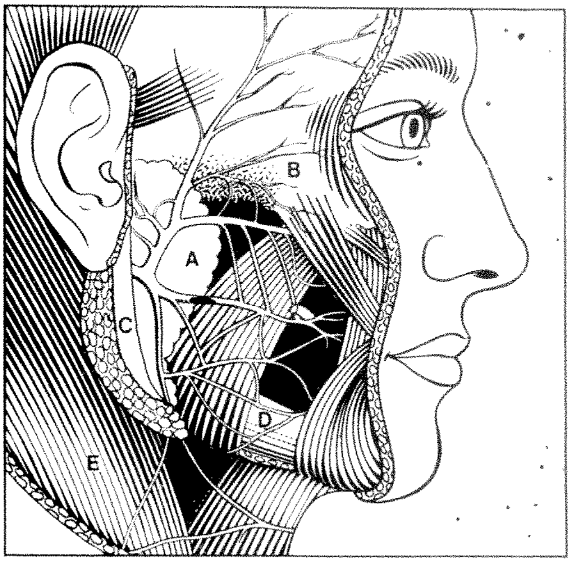
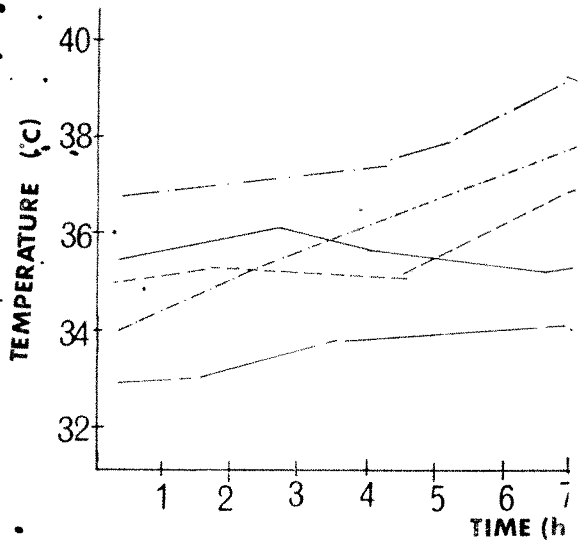
▼ REDRAWN VERSION REDUCED TO REQUIRED SIZE

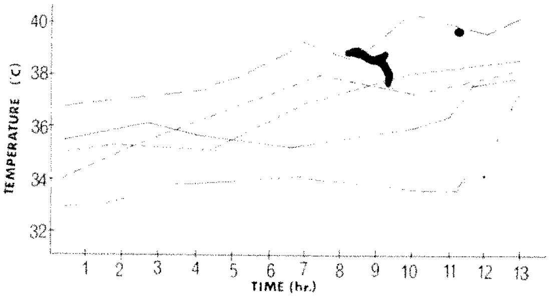


The original drawing, of which part is reproduced as drawn, has been carefully, if amateurishly, executed. It particularly illustrates the danger of the filling-in of detail when such a drawing is reduced in scale. The lettering has been inexpertly added, and for the *British Journal of Surgery* we prefer not to have the figure number on the drawing itself as it always occurs in the legend. The comparison of these two versions would repay careful study on the part of an artist.

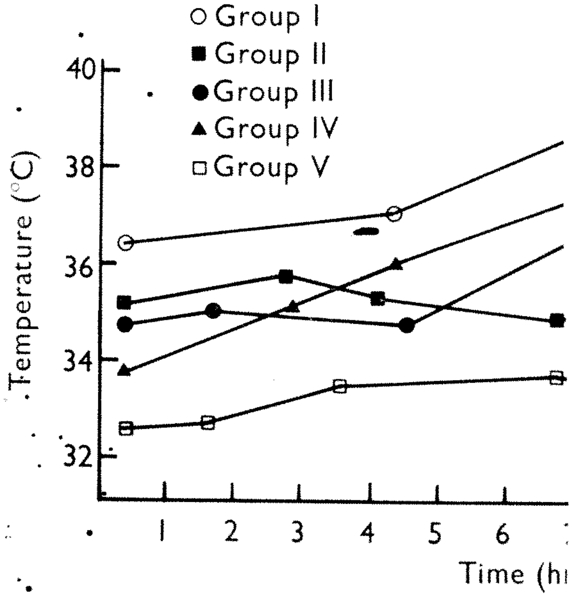


◀ SECTION OF ORIGINAL RECEIVED FROM AUTHOR

▼ ORIGINAL REDUCED TO REQUIRED SIZE

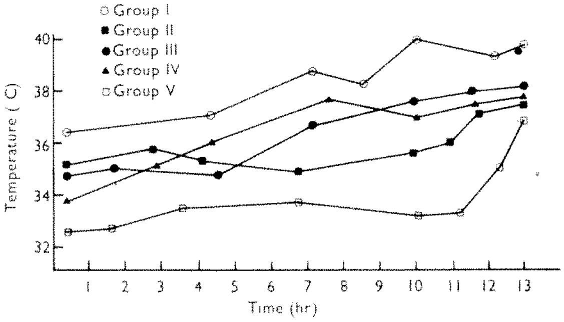


The section of the piece of original artwork shown above particularly illustrates the danger of using too light a weight of line, for it will be seen that when reduced to the appropriate size some of the lines have become so thin as not to reproduce evenly. The difficulty of maintaining accurate positioning of Letraset lettering is also shown in the numbers along the baseline The redrawn version of the artwork shown below indicates how much heavier the original needs to be to give really satisfactory reproduction at the reduced scale. A preferred method of differentiating between graph lines is also shown. A key to the five different curves has been added and the importance of this cannot be over-estimated.



◀ SECTION OF REDRAWN VERSION

▼ REDRAWN VERSION REDUCED TO REQUIRED SIZE



ligated in the vein and fixed to the skin by a suture. When no peripheral veins were available, catheters were inserted percutaneously into a major vein, and the subclavicular approach to the subclavian vein was the route most commonly used. A 30-cm, 21-gauge catheter in an 18-gauge needle (Venocath, Abbott Laboratories) was used for these insertions.

The location of the catheters was checked immediately after insertion by obtaining a portable chest X-ray while injecting 5 ml of sodium diatrizoate 50 per cent (Hypaque) through the catheter. Those shown unkinked and with their tip in the subclavian or innominate vein, the superior vena cava or the right atrium were accepted as suitably placed. Catheters that had failed to enter the central venous system or those that passed retrogradely into the interior jugular vein were replaced or manipulated and the X-ray repeated. Catheters that were coiled in the central venous system or too far advanced into the inferior vena cava or the heart were repositioned by withdrawing them an estimated distance. Under these circumstances a repeat X-ray was often omitted.

The insertion sites were dressed daily using polymyxin B, neomycin and mycostatin ointment. Catheters were not changed regularly and were removed only when no longer required or when some catheter complication developed.

Results

Ninety (75 per cent) of the 120 patients admitted during the period studied had one or more attempts to insert a central venous catheter. Eighty-one (90 per cent) of these had a catheter inserted into the central venous system after one to three attempts. Twenty-four (80 per cent) of 30 further attempts succeeded in locating a second catheter in the central venous system. During all these attempts, catheters that failed to enter the central veins were either stuck in the axillary vein or entered the internal jugular vein retrogradely. Direct puncture of major veins was used to insert 33·3 per cent of second catheters, but only 4·4 per cent of first catheters. *Table I* shows the success rate for each attempt for both first and second catheters.

All the catheters that did enter the central venous system were not located in suitable positions within it. The actual locations of these and the various sites from which they were inserted are shown in *Table II*.

Table I: CATHETERS LOCATED IN CENTRAL VENOUS SYSTEM AFTER VARIOUS INSERTION ATTEMPTS

Central venous catheter	Insertion attempt	No. of attempts	Catheters located in central veins No.	%
First	First	90	61	67·8
First	Second	29	14	48·3
First	Third	15	6	40
First	All attempts	134	81	60·5
Second	First	30	24	80
First and second	All attempts	164	105	64

Major veins ($n = 14$)	14 (100%)*	9 (64·3%)†	3	0	2
All sites ($n = 164$)	105 (64%)*	50 (47·6%)†	25	12	18

SVC, Superior vena cava.
* Percentage of all attempts from given insertion site.
† Percentage of all catheters located in central venous system from given site.

Table III: MECHANICAL COMPLICATIONS (TOTAL OF 105 CATHETERS)

Complication	No. of catheters	% of total catheters
Cracked catheters	13	12·4
Thrombophlebitis	4	3·8
Cardiac arrhythmias	2	1·9
'Lost' catheters	1	0·95
Cardiac tamponade	1	0·95

The locations given were those seen on the final X-ray taken and, although the malpositioned catheters were relocated by partial withdrawal, repeat X-rays were not done.

The catheters remained *in situ* from 1 to 65 days with an average duration of 12 days. While they were *in situ*, 21 (20 per cent) of the 105 catheters produced some mechanical complication (*Table III*).

Cracks in the catheters all occurred in the exposed portion and in most cases well away from the insertion site. These cracks were usually revealed by leakage of intravenous fluid. The cases with thrombophlebitis were all diagnosed clinically and catheters were sterile on culture when removed. Cardiac arrhythmias consisted of multiple premature ventricular contractions, which in one patient compromised cardiac output for a brief period. In both cases the catheter was located in the pulmonary outflow tract and the arrhythmia disappeared immediately when the catheter was withdrawn. The one 'lost' catheter broke and disappeared into the left basilic vein. A plain X-ray of the upper arm showed its retracted end situated 5 cm above the medial epicondyle. It was retrieved by local cutdown and the patient suffered no ill effects. The case of cardiac tamponade is the one described in the present case report.

Discussion

Cardiac tamponade due to perforation of the heart wall by a polyethylene catheter was first described by Brown and Kent (1956). Their patient died from cardiac tamponade due to perforation of the wall of the right ventricle by a fragment of a polyethylene catheter lost into the femoral vein 80 days earlier. Friedman and Jurgeleit (1968) then reported a fatal cardiac tamponade secondary to perforation of the wall of the right atrium by an intact polyethylene central venous catheter. Fourteen further cases of cardiac tamponade caused by perforation of the heart wall by intact polyethylene catheters have been reported (Barton et al., 1968; Kline and Hofman, 1968; Thomas et al., 1969; Brandt et al., 1970; Fitts et al., 1970; Adar and Mozes, 1971; Homesley and Zelenik, 1971; Bone et al., 1973). Defalque (1971) reported cardiac tamponade almost immediately after subclavian puncture, and at post-mortem the tip of the catheter was piercing the superior vena caval wall just below the site of pericardial reflection. McHenry and Hopkins (1968) reported cardiac tamponade caused by fluid infused through an open-ended pacing electrode which had perforated the wall of the right ventricle 60 hours after insertion. All but one (Defalque, 1971) of these accidents conform to a very similar pattern which is also true of the case reported in this paper. The polyethylene catheters were introduced through arm veins, their locations after insertion were either not checked radiologically or they were located in the right atrium, the patients were asymptomatic for periods of 30 minutes to 9 days and then each suffered a rapid drop in arterial blood pressure. The fluid found in the pericardial sac was the same as that being infused via the catheter, and varied from 200 to 1000 ml in volume. Three patients (Barton et al., 1968; Thomas et al., 1969; Brandt et al., 1970) were resuscitated after aspiration of the pericardial space but they subsequently died, having suffered irreversible brain damage. Two cases caused by polyethylene catheters (Thomas et al., 1969; Brandt et al., 1970) and 1 case caused by fluid infused through a pacing electrode (McHenry and Hopkins, 1968) made full recoveries after aspiration of the fluid.

Although this form of cardiac tamponade is rare, the mortality rate it carries is distressingly high. The problem should be preventable by locating all central venous catheters outside the heart.

The review of catheter locations presented in this paper shows a high incidence of catheter malposition which includes failure to enter the central venous system and malposition within the central veins. Fifty-nine (39·9 per cent) of 150 catheters inserted via peripheral arm veins lodged in the axillary, the cephalic or the internal jugular veins. After manipulation or replacement only 9 (10 per cent) of the 90 patients did not have a catheter in the central venous system. Although we found that this form of catheter malposition was not a problem with insertion by major vein puncture, we have refrained from using it as our first choice of insertion site, as it has been associated with dangerous complications (Smith et al., 1965; Schapira and Stern, 1967; Wiseheart et al., 1972). Failure to enter the central venous system will not cause cardiac tamponade but unless it is detected unreliable or misleading central venous pressure measurements will be recorded (Gilday and Downs, 1969; Dietel and McIntyre, 1971; Langston, 1971; Thomas, 1972).

Catheter malposition within the central venous system can, however, cause dangerous mechanical complications as well as unreliable central venous pressure readings. This review of 105 catheters showed that 25 (23·8 per cent) were located in the right atrium, 12 (11·4 per cent) were in other intracardiac sites and 18 (17·1 per cent) were coiled in the superior or inferior vena cavae. Some of this malpositioning may have been due to the use of a 95-cm catheter. Fourteen (60·9 per cent) of the 23 catheters inserted from the left arm but only 23 (35·9 per cent) of the 64 inserted from the right arm were located in the superior vena cava. These long catheters were probably inserted too far but the extra length was accommodated better in the longer venous route from the left arm. A 52·5-cm catheter is now used and not more than 45 cm are inserted until a check X-ray is done. There is considerable confusion in the literature about where central venous catheters should be located. An early description of the use of central venous pressure measurements specified that the catheter tip should lie at the junction of the innominate veins and the superior vena cava, and that the inferior vena cava should be avoided (Wilson et al., 1962). However, some recent writers (Bethel, 1972; Colvin et al., 1972) have suggested that the right atrium should be used routinely, and others (Bell et al., 1973) use the superior vena cava and the right atrium as suitable positions. Guyton and Jones (1973) has shown that the venous pressure at any site within the great veins or venae cavae is within 1 mm Hg of that in the right atrium. The subclavian vein usually has a pair of valves situated within 2 cm of its termination (Warwick and Williams, 1973), and Thomas (1972) suggested that catheters should be advanced into the subclavian vein beyond the narrow, easily compressed costoclavicular segment where arm movement may induce vein wall trauma by the tip of the catheter. Bansmer et al. (1958) showed that catheters in the inferior vena cava were associated with a very high thrombosis rate, and Wilson et al. (1962) suggested that venous pressures within the inferior vena cava are unreliable in the presence of abdominal distension. From these facts and our experience of cardiac perforation by an intracardiac catheter we suggest that all central venous catheters should be located in the innominate (brachiocephalic) veins or the upper half of the superior vena cava.

Although the original 95-cm catheter had a radio-opaque marker line, it was not possible to identify the catheter in the mediastinal shadow of the portable chest X-rays used in the intensive care unit. The catheter now used (Sorenson Intrafusor, 52·5 cm) has a better defined marker line that can be identified easily on plain chest X-rays. This provides a useful check on catheter position during the time that it is *in situ* without repeating radio-opaque dye injection.

Cracked catheters were the most frequent mechanical complication noted in this review. These are not dangerous if detected early and replaced, but Wellman et al. (1968) found that they were a frequent forerunner of 'lost' catheters. The one lost catheter in this review occurred after a cracked catheter had been repaired by removing the damaged portion and reconnecting the intravenous fluids line through a blunt needle. This practice is dangerous and has been discontinued. All cracked catheters should be removed and replaced if there is still need for a central venous line.

Conclusions

The following guidelines for the insertion and use of central venous catheters have been formulated from the data provided by this review and the experience of a fatal cardiac tamponade:

1. Catheters should be inserted via the basilic vein in the antecubical fossa unless the operator is skilled in performing subclavian puncture.
2. A 52·5-cm catheter with an adequate radio-opaque marker line should be used, and not more than 45 cm of catheter inserted until the first check X-ray is taken.
3. The catheter's location should be checked radiologically after insertion and each manipulation.
4. The catheter should be located, without coiling, in the innominate veins or the upper half of the superior vena cava.
5. The insertion site should be kept covered and dressed daily using a topical antibiotic ointment.
6. Cracked catheters should be removed and not repaired.

Acknowledgements

We extend our grateful thanks to the resident medical and nursing staff of the Intensive Care Unit who cared for these patients, to the filing room staff of the Radiology Department for their help with location of the X-rays and to Ms Kathy Tropeau who typed the manuscript.

The response of the lower oesophageal sphincter to maximal doses of pentagastrin

L. M. TRINDADE, I. L. ROSENBERG, Z. J. ROZYCKI AND G. R. GILES*

SUMMARY

Measurements of the lower oesophageal sphincter pressure and gastric secretion were made in patients with dyspepsia but no reflux and in patients with a hiatus hernia and reflux in response to a near maximal dose of pentagastrin. Patients with hiatus hernia had lower resting sphincter pressures than those with dyspepsia. The magnitude of the pressure rise following pentagastrin was related to the resting tone of the sphincter. However, in terms of percentage increase over resting sphincteric pressure, patients with dyspepsia and patients with a hiatus hernia had similar responses.

IT is still conventional to attribute the symptoms of gastro-oesophageal reflux to the presence of a hiatus hernia. However, there has been considerable scepticism concerning the role of the hiatus hernia in producing these symptoms (Pope, 1970; Cohen and Harris, 1971). Some current views would suggest that the single most important factor in maintaining competence at the cardia and in preventing gastro-oesophageal reflux is the tone and responses of the lower oesophageal sphincter (Castell and Levine, 1971; Cohen and Harris, 1971). This being so, there would be an advantage in developing a reproducible test of sphincteric function which might aid the management of an individual patient. Previous tests of sphincteric function have largely relied upon the pressure changes in the lower oesophageal sphincter in response to mechanical stresses, for example, straight leg raising or from a tight abdominal binder (Lind et al., 1966; Winans and Harris, 1967). More recently, Roszkowski et al. (1973) have investigated the pressure changes of the lower oesophageal sphincter in response to the endogenous gastrin release induced by a test meal stimulus and were able to show diminished responses in patients with gastro-oesophageal reflux. This paper reports an investigation of the responses of the lower oesophageal sphincter and gastric secretory responses to near maximal doses of pentagastrin in patients with dyspepsia or gastro-oesophageal reflux.

Materials and methods

Simultaneous measurement of the lower oesophageal sphincteric pressure and gastric acid secretion was carried out using a multiple tube system. Gastric secretion was aspirated through a size 12 FG plastic tube by continuous suction. Bonded on opposite sides of the nasogastric tube were two fine polyethylene tubes of 1·2 mm internal diameter and 1·4 mm external diameter. One of these fine tubes had a side hole of 1·2 mm diameter at 15 cm from the distal end of the nasogastric tube and the other tube had a similar hole at 20 cm from the distal end (Fig. 1). The fine polyethylene tubes were used for pressure measurement and were perfused continously with normal saline at a rate of 0·6 ml/min. The tubes were connected via pressure transducers to amplified galvanometers, the deflections of which were recorded on ultraviolet-sensitive paper.

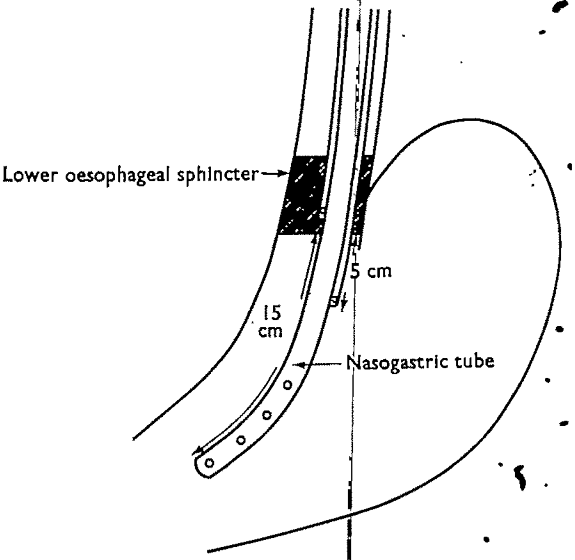

Fig. 1. Position of the manometric tubes in the area of the lower oesophageal sphincter and the gastric fundus. The nasogastric tube is connected to a continuous suction pump for collection of gastric secretion.

After a 12-hour fast the subjects swallowed the tube system into the stomach. The tubes were positioned so that the lowest side hole in the pressure-recording tubes faced the right lateral aspect of the oesophagus. After emptying the stomach of the resting content of gastric juice, the tube system was withdrawn in cm steps with a pressure recording at each interval. This resulted in a pressure profile of the lower oesophageal sphincter, identifying its position with regard to the point of respiratory reversal and the length of amplitude of the sphincteric pressure zone. The tube system was then repositioned so that the upper pressure recording side hole was placed at the point of maximum sphincteric pressure. The lower side hole was situated 5 cm below in the gastric fundus and the aspirating holes of the nasogastric tube 15 cm below in the body of the stomach.

---

* University Department of Surgery, St James's Hospital, Leeds.

Basic gastric secretion was collected for 1 hour in 10-minute aliquots, following which the suction was disconnected and basal sphincteric pressures recorded for 5 minutes. The stomach was again emptied and a deep intramuscular injection of pentagastrin (ICI) given at a dose of 6 μg/kg. Sphincteric pressures were recorded for periods of 2 minutes at 0, 4, 8, 10, 15, 20, 30, 40, 50 and 60 minutes after the injection. In between these periods of pressure recording, gastric secretion was collected in 10-minute aliquots for 1 hour. Simultaneous gastric aspiration and prolonged pressure recordings were not feasible because of the contamination of the gastric samples by the saline perfusing the manometric tubes.

Gastric samples were titrated against 0·1-N sodium hydroxide using Töpfers reagent as an indicator to a pH of 5·6 and the results expressed in terms of concentration (mEq/l) and acid output (mEq/hr). The peak acid output was calculated from the highest two consecutive aliquots collected (Mason and Giles, 1969).

The pressure recordings of the lower oesophageal sphincter were analysed with regard to the sphincteric pressure, and the pressure changes which followed the administration of pentagastrin. All results are expressed in terms of mm Hg.

Combined manometric and gastric secretion studies were carried out on 16 patients with dyspepsia (12 with a duodenal ulcer) and 13 patients with a radiologically demonstrable hiatus hernia. Of the patients with hiatus hernia, 9 were sufficiently symptomatic to warrant surgical repair and the remainder had no symptoms of gastro-oesophageal reflux.

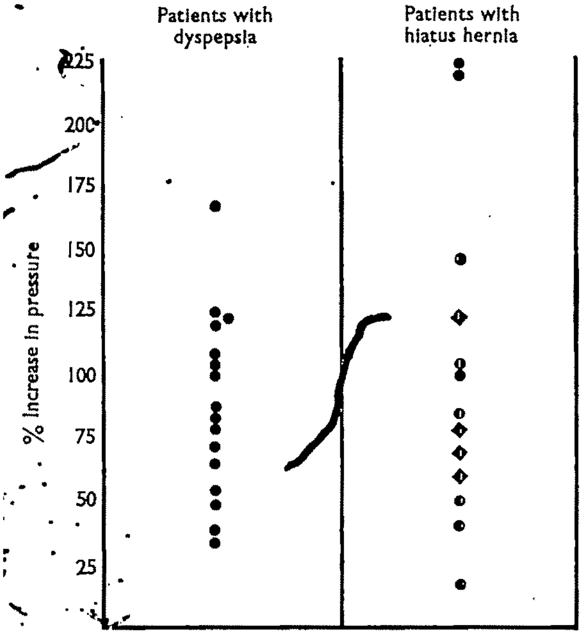

Fig. 2. Maximum percentage increase in the lower oesophageal sphincteric pressure above basal levels after stimulation with pentagastrin 6 μg/kg i.m. The sphincter pressure changes in 4 patients with an asymptomatic hiatus hernia are shown as diamonds.

Results

All the subjects tested were found to have an increase in sphincteric pressure following pentagastrin administration and to show evidence of raised gastric acid output. The peak of the sphincteric pressure response was reached after 8–30 minutes and thereafter declined towards basal levels. This variability in the timing of the pressure peak was assumed to be due to an inconsistent absorption of the intramuscular pentagastrin and bore no relationship to the resting pressures of the lower oesophageal sphincter. However, the peak sphincteric pressure did appear well correlated with the peak of gastric acid output.

1. *Patients with dyspepsia but without hiatus hernia or radiologically diagnosable reflux*

a. Lower oesophageal sphincter pressures: The mean resting sphincter pressure for the 16 patients was 21·6 ± 6·4 mm Hg (range 9·0–34 mm Hg). The mean peak of lower oesophageal sphincter pressure reached 39·6 ± 10·4 mm Hg and ranged from 23·5 to 55·8 mm Hg. The amplitude of the peak lower oesophageal sphincter pressure after pentagastrin was directly related to the resting pressure of the lower oesophageal sphincter ($\gamma = 0{\cdot}8100$, $P < 0{\cdot}001$). In order to allow comparisons between the two groups of patients the peak of the pressure response can be expressed as a percentage change from the resting lower oesophageal sphincter pressure. The mean percentage increase was 87·43 ± 36·3 per cent and individual percentage increases are shown in *Fig.* 2.

Six patients in this group admitted on close questioning to occasional heartburn but without other reflux symptoms. The mean resting pressure for the 6 patients was 20·0 ± 6·3 mm Hg and the mean maximum pressure increase after pentagastrin was also similar to the whole group at 38·2 ± 10·6 mm Hg.

b. Gastric acid secretion: The mean basal acid secretion was 4·64 ± 4·6 mEq/hr, ranging from 0 to 17·3 mEq/hr. The mean peak acid output calculated in the manner described was 39·3 ± 16·5 mEq/hr and ranged from 15·5 to 67·9 mEq/hr. The 6 patients who had heartburn as a symptom appeared to have significantly high mean basal secretion at 8·2 ± 5·6 mEq/hr ($t = 3{\cdot}04$, $P < 0{\cdot}01$) and significantly higher peak acid output at 46·1 ± 17·8 mEq/hr ($t = 3{\cdot}03$, $P < 0{\cdot}01$).

There was no correlation between the resting lower oesophageal sphincter pressures and the basal acid output ($\gamma = 0{\cdot}0201$) or between the maximum lower oesophageal sphincter responses and the peak acid output ($\gamma = 0{\cdot}0503$).

2. *Patients with a symptomatic hiatus hernia and free reflux*

a. Lower oesophageal sphincter pressures: The mean resting pressure of the lower oesophageal sphincter of these 9 patients was 17·9 ± 5·4 mm Hg, ranging from 8·1 to 26·5 mm Hg. This is not significantly different from the patients with dyspepsia ($t = 1{\cdot}42$, $P > 0{\cdot}1$). The mean peak of lower oesophageal sphincter pressure after pentagastrin was 34·1 ± 13·6 mm Hg (range 22–62 mm Hg), which was not significantly different from the patients with dyspepsia ($t = 0{\cdot}87$, $P > 0{\cdot}3$). Finally, the mean percentage increase in lower oesophageal sphincter pressure over the resting pressure was 110·2 ± 79·0 and was extremely variable (*Fig.* 2), ranging from 15 to 23·8 per cent. With this group of patients the peak pressure response of the lower oesophageal sphincter after pentagastrin did not significantly correlate with the resting pressure ($\gamma = 0{\cdot}40$, $P > 70{\cdot}4$).

b. Gastric acid secretion: The mean basal acid output for the group was 5·4 ± 5·4 mEq/hr, ranging from 0·3 to 18·2 mEq/hr. The mean peak acid output was 36·0 ± 22·1 mEq/hr (range 8·1–79·1 mEq/hr). These values clearly do not significantly differ from the group of patients with dyspepsia.

3. *Patients with a hiatus hernia but without reflux*

There were 4 patients in this group and the mean resting lower oesophageal sphincter pressure was 42·0 ± 12·5 mm Hg, ranging from 31 to 60 mm Hg. The peak pressure of the lower oesophageal sphincter after pentagastrin averaged 77·3 ± 24·6 mm Hg (range 55–108 mm Hg). The mean percentage increase in lower oesophageal sphincter pressures was 85·8 ± 23·6 per cent (*Fig.* 2), ranging from 66 to 120 per cent. Since this group was small, worthwhile statistical comparison with the other groups of patients was not possible.

The mean basal secretion of these 4 patients was 4·9 mEq/hr (range 0–9·2 mEq/hr) and the mean peak acid output was 32·9 mEq/hr (range 17·1–47·5 mEq/hr).

Discussion

Gastro-oesophageal competence may depend upon certain anatomico-spatial relationships at the diaphragmatic hiatus and upon the tone of the lower oesophageal sphincter. Whether any of these factors has an overriding importance is debatable, though some workers have suggested that the tone of the lower oesophageal sphincter alone will determine the presence or absence of gastro-oesophageal reflux (Castell and Levine, 1971; Cohen and Harris, 1971). While this may be the position in some cases, it is clear that the majority of patients with reflux have an associated hiatus hernia. Equally, it must be admitted that the tone exerted by the lower oesophageal sphincter may prevent reflux in some patients with hiatus hernia as shown by 4 patients in the present study. It is these inconsistencies which make it advantageous to investigate patients with symptoms of reflux by both manometric and radiological techniques.

The tone of lower oesophageal sphincter under resting conditions has been extensively investigated by techniques which measure the 'squeeze' of the sphincter (Pope, 1967). It has been suggested that resting pressures of less than 10 mm Hg are always associated with reflux (Cohen and Harris, 1971), but this is not the experience of other workers (Haddad, 1970; Brennan et al., 1974). This being so, it seems more appropriate to investigate the reaction of the lower oesophageal sphincter to situations likely to be associated with reflux.

It has been shown that the lower oesophageal sphincter pressure rises during pregnancy (Lind et al., 1968) and in patients with ascites (Simpson and Conn, 1960). The response of the lower oesophageal sphincter to raised intra-abdominal pressure induced by straight leg raising was studied by Lind et al. (1966). Cohen and Harris (1971), using a similar stimulus, were able to show a strong correlation between the occurrence of reflux and a failure of the lower oesophageal sphincter to produce increases in lower oesophageal sphincter pressure which matched the rise in abdominal pressure.

Giles et al. (1969) have shown that the lower oesophageal sphincter pressure is strongly affected by both endogenous and exogenous gastrin. Cohen and Lipschutz (1971) have since demonstrated that the smooth muscle of the lower oesophagus is particularly responsive to circulating gastrin when compared with the muscle layers of the stomach and middle oesophagus. Dose–response curves of the lower oesophageal sphincter to graded intravenous doses of pentagastrin have been constructed and follow a characteristic sigmoid curve (Cohen and Lipschutz, 1971), achieving maximum sphincteric pressure increases of 460 per cent above the resting tone with pure gastrin and 360 per cent above the resting levels with pentagastrin (Lipschutz et al., 1973). Increases of this magnitude were not seen in the present study either in patients with a hiatus hernia or in patients with dyspepsia. These patients are clearly not a control group of normal subjects and thus the responses of the lower oesophageal sphincter may have been altered by their gastro-intestinal disease. However, a more probable explanation is the mode of pentagastrin administration, which in our study was given intramuscularly. Though the dose of 6 μg/kg of pentagastrin intramuscularly has been found to produce near maximal levels of gastric secretion (Johnston and Jepson, 1967; Mason and Giles, 1969) it is probable that serum levels of pentagastrin do not reach the peak concentrations seen after intravenous injections.

The responses of the lower oesophageal sphincter to pentagastrin, in terms of absolute pressure and percentage change, were somewhat higher in the dyspeptic subjects than in the patients with a symptomatic hiatus hernia. However, these differences were not statistically significant and clearly the lower oesophageal sphincter responsiveness to pentagastrin in patients with a hernia approaches normality as judged by this test. The single most important factor in determining the response of the lower oesophageal sphincter to exogenous gastrin would seem to be the resting tone of the sphincter, a point commented upon previously (Cohen and Lipschutz, 1971).

In a study of the lower oesophageal sphincter responses to endogenous gastrin released by a meat extract test meal, Roszkowski et al. (1973) were able to show a clear distinction between patients with symptomatic reflux and control subjects. This distinction has not been paralleled in the present study, where the response to exogenous gastrin by patients with reflux appears normal. Similar findings have been reported by Lipschutz et al. (1973) and have led them to postulate that diminished gastro-oesophageal competence is the result of a diminished release of endogenous gastrin and not necessarily a primary dysfunction of the lower oesophageal sphincter.

Levels of gastric acid secretion in patients with gastro-oesophageal reflux have been variably reported. Some workers have shown gastric hypersecretion (Herrington, 1962; Casten, 1967), while other workers have shown no difference from control subjects (Williams et al., 1967; Silber, 1969). It is probable that high acid secretion in patients with gastro-oesophageal reflux will be found mainly in patients with an associated peptic ulcer.

The values of gastric secretion found in the patients in the present investigation clearly reflect the symptomatology and pathology of the two clinical groups. There does not appear to be any firm correlation between the levels of basal acid secretion and peak acid output and the pressures exerted by the lower oesophageal sphincter. However, studies of gastric acid secretion in patients with a hiatus hernia may be of assistance to surgeons, in order that the surgical repair can be supplemented where necessary by a procedure which will reduce the acid secretion. Studies using a combined test of manometry and gastric secretion are thus potentially of clinical value. However, since the use of pentagastrin does not readily distinguish lower oesophageal spincter dysfunction in patients with reflux, it will be necessary to continue the use of a test meal system. In practical terms, failure of the lower oesophageal sphincter to respond to either form of stimulus should warn the surgeon that simple hiatus hernia repair may not be successful and indicates the need for some form of surgical reconstruction at the cardia.

Relationship between changes in plasma gastrin and lower oesophageal sphincter pressure after meals

I. W. McCALL, R. F. HARVEY, CAROLINE J. OWENS AND B. G. CLENDINNEN*

SUMMARY

Changes in plasma gastrin and lower oesophageal sphincter pressure were measured in 20 subjects after a standard protein meal. Significant increases in both gastrin and sphincter pressure were seen. Peak gastrin response occurred an average of 19·5 minutes and peak lower oesophageal sphincter response 43·0 minutes after the meal. Both gastrin and sphincter pressure showed a wide spectrum of response. In 5 subjects there was no appreciable rise (< 5 pg/ml) in plasma gastrin after the meal, and 3 of these had symptoms of oesophageal reflux. In this group there was only a small but nevertheless significant rise in lower oesophageal sphincter pressure (mean pressure rise 18·0 per cent of fasting value, $P < 0.05$). Greater increases in sphincter pressure (mean rise 54·2 per cent, $P < 0.005$) were seen in subjects with a moderate (up to 50 pg/ml) rise in plasma gastrin, and those with the most marked gastrin response (> 50 pg/ml) showed the greatest rise in pressure (mean rise 80·3 per cent, $P < 0.0025$).

These results suggest that endogenous plasma gastrin is the main stimulus to the rise in lower oesophageal sphincter pressure after food. Subjects with a poor gastrin response to the meal have only a small increase in sphincter pressure and as a result may be more liable to develop gastro-oesophageal reflux.

REFLUX of gastrin contents into the oesophagus is normally prevented by a high pressure zone (the lower oesophageal sphincter) at the gastro-oesophageal junction (Pope, 1967; Winans and Harris, 1967; Cohen and Harris, 1970). After meals there is an increase in lower oesophageal sphincter pressure (Giles et al., 1969; Castell and Harris, 1970; Nebel and Castell, 1972). Similar increases are seen after intravenous injections of pentagastrin and gastrin (Giles et al., 1969; Cohen and Lipshutz, 1971), indicating that endogenous gastrin may be responsible for the increased sphincter pressure after food. Acidification of a meal (which inhibits endogenous gastrin release) prevents the usual pressure rise (Nebel and Castell, 1972).

Lipshutz et al. (1973) demonstrated that subjects with symptomatic gastro-oesophageal reflux have an abnormally small increase in lower oesophageal sphincter pressure after food when compared with control subjects, whereas the response of the sphincter to injected pentagastrin is normal. This suggests that incompetence of the lower oesophageal sphincter might be due to a defect in the release of endogenous gastrin. In order to test this hypothesis we have measured and compared the changes in lower oesophageal sphincter pressure with direct measurements of endogenous plasma gastrin after a standard protein meal.

Materials and methods

Changes in lower oesophageal sphincter pressure and endogenous plasma gastrin after a standard meat extract meal were measured in 20 volunteers (9 normal subjects, 8 generally well patients with no evidence of gastro-intestinal disease who were convalescing from minor surgical operations and 3 patients with symptomatic gastro-oesophageal reflux). All the subjects had fasted for at least 6 hours before the test.

Lower oesophageal sphincter pressures were measured by using catheters of 1·2 mm internal diameter constantly perfused with 1·0 ml/minute of water and connected to a Devices M19 recording system. The tubes were passed into the stomach, then slowly withdrawn through the sphincter, this resulting in a pressure profile (*Fig.* 1). The figure taken was the difference between the maximum sphincter pressure and the pressure in the gastric fundus. The fasting level was taken from the mean of three readings and all subsequent values were expressed as a percentage of this fasting level.

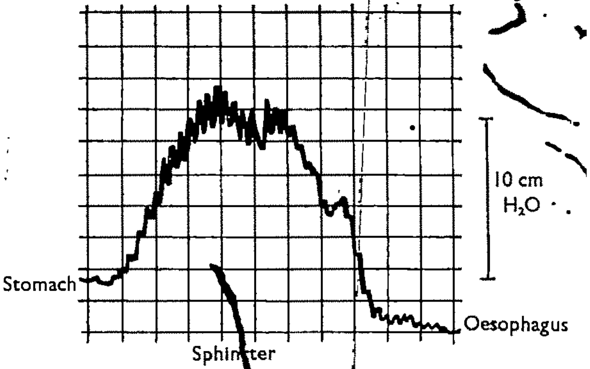

Fig. 1. Pressure 'profile' obtained by withdrawing the pressure-recording catheter slowly from the stomach to the oesophagus.

Venous blood samples for gastrin estimation were taken from an indwelling catheter and the plasma separated within 2 hours and frozen at −20 °C until assayed. A radio-immunoassay with double-antibody separation was employed (Jackson et al., 1972), using a rabbit antibody to synthetic human gastrin 1

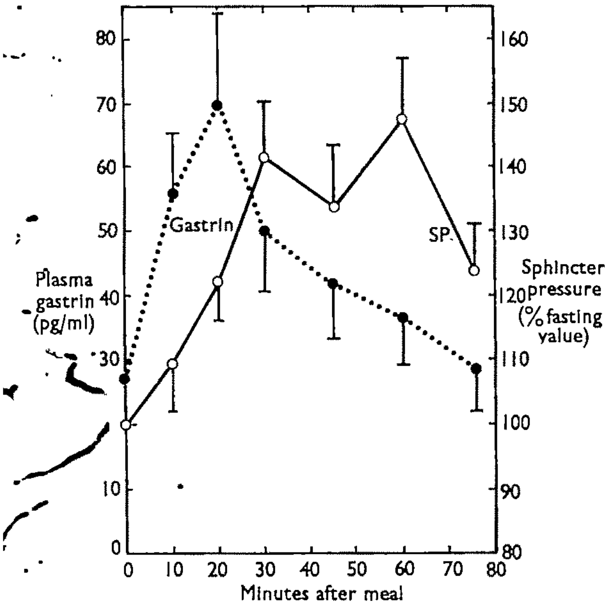

Fig. 3. Changes in sphincter pressure and plasma gastrin after the test meal (all subjects). Mean values and standard errors are shown.

(residues 2–17). All the samples were assayed in triplicate, the mean of the triplicates being taken as the serum gastrin level. Intra-assay variation was less than 10 per cent and interassay variation up to 15 per cent. The lower limit of sensitivity of the assay was 10 pg/ml of plasma.

After taking the fasting pressure measurements and fasting blood for gastrin estimation, all the subjects drank a standard meal consisting of 8·0 g of meat extract (Bovril) dissolved in 300 ml water buffered to pH 7·0 with approximately 1·0 g TRIS (hydroxymethyl) aminomethane (Sigma). Measurements of lower oesophageal sphincter pressure and samples for plasma gastrin were then obtained 5, 10, 15, 20, 30, 45, 60 and 75 minutes after this meal.

Results

Following the test meal there were significant increases in both plasma gastrin (from a mean fasting level of 27·3 ± 6·8 (s.e.) to a peak of 74·4 ± 13·7 pg/ml, $P < 0·005$) and in lower oesophageal sphincter pressure (mean increase 53·0 ± 9·4 per cent of fasting value, $P < 0·001$). The maximal mean rise in plasma gastrin occurred within 20 minutes of taking the Bovril in all but 3 subjects (mean 19·5 ± 2·4 minutes), but the maximal mean response of the lower oesophageal sphincter pressure occurred some time later (mean 43·0 ± 4·1 minutes after the Bovril). The changes for the subjects with the greatest gastrin rise and for the whole group are shown in *Figs.* 2 and 3 respectively.

The response to the meal of both the plasma gastrin and lower oesophageal sphincter pressure varied widely. In a group of 5 subjects in whom plasma gastrin levels did not change appreciably (mean levels 43·0 ± 23·7 pg/ml fasting, 43·6 ± 22·1 pg/ml postprandial, maximum increase 4 pg/ml) there was only a small though significant rise in lower oesophageal sphincter pressure (18·0 ± 8·2 per cent, $P < 0·05$). This was considerably less than that seen in subjects with a significant rise in plasma gastrin in whom the oesophageal sphincter showed a peak rise of pressure of 64·7 ± 10·7 per cent ($P < 0·025$). In order to analyse the results in more detail the subjects showing a significant gastrin response were divided into two further groups (*Table I*). Those with a moderate rise of 19–50 pg (9 subjects) showed a more marked pressure increase of 54·2 ± 14·2 per cent than those with no gastrin response, and subjects with rises in

† Including 3 patients with symptomatic gastro-oesophageal reflux.

gastrin levels of more than 50 pg/ml showed an even more striking increase in lower oesophageal sphincter pressure (mean 80·3 ± 15·2 per cent).

The correlation between peak gastrin rise and peak lower oesophageal sphincter pressure rise in individual subjects did not quite reach significant levels ($r = 0{\cdot}37$, $n = 20$, $0{\cdot}05 < P < 0{\cdot}10$). However, when the 2 subjects with the greatest rises in gastrin (157 and 221 pg/ml) were excluded the correlation was significant ($r = 0{\cdot}52$, $n = 18$, $P < 0{\cdot}05$). This may indicate that the relationship between peak pressure response and peak rise in plasma gastrin is not strictly a linear one.

The 3 patients with symptomatic gastro-oesophageal reflux were all in the group of 5 subjects who showed no increase in plasma gastrin and little rise in sphincter pressure after the meal.

Discussion

The lower oesophageal sphincter is known to be a major factor in the prevention of gastro-oesophageal reflux (Pope, 1967; Winans and Harris, 1967; Cohen and Harris, 1970), and sphincter pressure may be more important than the exact location of the gastro-oesophageal junction, suggesting that a simple positional change, as seen with hiatus hernia, is not the cause of gastro-oesophageal reflux (Cohen and Harris, 1971). It has recently been confirmed that patients with symptomatic gastro-oesophageal reflux have a smaller sphincter pressure than do control subjects, both basally and also after standard stimuli (e.g. intragastric alkali and glycine) (Lipshutz et al., 1973).

The role of gastrin in maintaining lower oesophageal sphincter strength is now well established (Giles et al., 1969; Castell and Harris, 1970; Cohen and Lipshutz, 1971; Lipshutz et al., 1972), and it follows that gastro-oesophageal hypotension and incompetence might be due to some defect in the action of gastrin on the lower oesophageal sphincter. There are several possible ways in which this might come about. The sphincter in patients with reflux might in some way be inherently abnormal. However, patients with symptomatic reflux show a similar sphincter response to direct muscle stimulation by a parasympathomimetic drug (bethanechol chloride) and a cholinesterase inhibitor (edrophoninum chloride) to control subjects (Lipshutz et al., 1973). The sphincter might be inherently normal but for some reason resistant to the action of gastrin. However, dose–response curves of lower oesophageal sphincter pressure to exogenous intravenous pentagastrin obtained by these same workers were similar in patients with reflux and in controls. The third possibility is that the sphincter of the patient with reflux receives an inadequate stimulus to contract. In support of this theory Lipshutz and his colleagues (1973) have shown that in such patients the pressure response of the sphincter to oral stimuli designed to release endogenous gastrin is reduced. Our finding that the pressure response of the lower oesophageal sphincter is proportional to the gastrin response after a meal in the majority of subjects supports this hypothesis. Of the 5 subjects showing no appreciable rise in plasma gastrin in response to the meal, 3 had symptomatic gastro-oesophageal reflux.

It is of interest that the 5 subjects who did not show a rise in serum gastrin after the meal nevertheless showed a small but significant increase in lower oesophageal sphincter pressure (*Table I*). This indicates that although gastrin may be the main stimulus to the rise in sphincter pressure after food, it is not the only one. Other nervous or hormonal factors may have some importance in subjects who for some reason do not show a normal endogenous gastrin response.

The time lag between the peak endogenous serum gastrin concentration and the peak increase in lower oesophageal sphincter pressure is also of interest, and we are not aware that it has been reported previously. A degree of delay might be expected, as gastrin in blood is presumably not active until it has come into contact with and become bound by specific receptors on the cells of the target tissue. Little is known of this process in the case of gastrin.

Our results, taken in conjunction with those of previous workers, suggest that gastro-oesophageal hypotension and associated incompetence may be due to a defect in endogenous gastrin release by the stomach. If confirmed, this might have important therapeutic implications in the management of patients with gastro-oesophageal reflux.

Acknowledgements

The generous gift of antigastrin antibodies by Dr J. C. Thompson, USA, is gratefully acknowledged. We also thank the volunteers who took part in the study and physicians and surgeons of the United Bristol Hospitals who allowed us to study their patients. This work was supported in part by the Medical Research Council.

Circumstances and accidents, such as I have related, rendered it very difficult however to procure good qualified surgeons for the army, and a curious expedient was resorted to in consequence. Political economists say that when the demand for tea, coffee, sugar, cotton, &c. &c. is greater than the supply, the price will increase, and that human labour ought to be regulated by the same rule; the authorities in England thought however otherwise, and instead of increasing the price, or smoothing away the difficulties, they deteriorated the article, and as surgeons could not be found qualified to kill or cure by commission, they thought it right to take those of an inferior description, and give them only a warrant, as they do to boatswains and gunners on board-ship. I do not know whether this bright idea originated with the Government or the Army Medical Board; but when elicited, it seemed to please all parties, and a certain number of gentlemen thus warranted to do business came out to Spain. I had some of them at San Andero, where I was for a couple of months. One poor fellow having called to report his arrival, I desired him to sign a paper descriptive of his qualifications. This I found he could scarcely do, the letters very much resembling pot-hooks; which he attributed to sea-sickness, in which I sympathized with him, my own stomach being easily unshipped by a very moderate view of blue salt water. I therefore sent him to live at one of the fever-hospitals, to do duty for a few days, until I might see what he was made of.

A survey of the results of the Boerema anterior gastropexy for hiatus hernia over a 4-year period

C. J. DAVIES*

SUMMARY

The results obtained by using the Boerema anterior gastropexy for symptomatic hiatus hernia over a 4-year period are reviewed. All 68 patients were operated upon by the same surgeon. The success rate as judged by relief of the patients' symptoms was 90 per cent.

It is felt that the operation has advantages such as to justify its wide use.

IN 1972 the results were published of 101 operations for symptomatic hiatus hernia (Magary, 1972). All the operations had been done in Bath by the same surgeon. It emerged from this comparison of methods of repair that the Boerema anterior gastropexy had significantly less clinical failures. It also had the merit of being simple and could be performed quickly. For these reasons the Boerema procedure gained preference, and it has been used exclusively since 1970 by the surgeon concerned (Mr H. T. John, Consultant Surgeon, Bath Clinical Area). The results of this procedure over a 4-year period have now been reviewed.

Materials and methods

In the years 1968–72, 72 patients underwent a Boerema repair for symptomatic hiatus hernia confirmed by radiology and/or oesophagoscopy. A questionnaire was sent to each patient; 3 did not reply and 1 questionnaire was returned marked 'Gone away', leaving 68 patients available for this survey.

An analysis of these patients according to sex and age (*Table I*) shows that 47 out of the 68 patients (nearly 70 per cent) are over 50 years old, females outnumber males by more than 2 to 1 and half the patients are females over the age of 50.

Examination of the case notes showed that 6 patients had undergone previous surgery for hiatus hernia. The details of these and other relevant operations are given in *Table II*.

At laparotomy it was common to find pathology as well as the hiatus hernia (*Table III*), and several operative procedures were carried out in addition to the Boerema repair (*Table IV*).

Magary (1972) used a system of grading of severity of symptoms due to hiatus hernia (*Table V*) and this has been adhered to. The patients were sent a questionnaire which was framed in such a way that the patients themselves selected the grade into which their symptoms fell. In an attempt to isolate the symptoms related to hiatus hernia and gastro-oesophageal reflux, they were asked also to state whether any symptoms they had were the same as or different from those of which they complained preoperatively. In addition, they were asked to describe their symptoms.

The preoperative grading of symptoms (*Table VI*) was done by reference to the referral letter and the outpatient and inpatient case histories. Postoperative gradings were made from the case notes, data from a previous survey involving 39 of these patients (Magary, 1972) and the questionnaire for the present study to assess the current state of the patients' health. The patients undergoing surgery with grade 2 symptoms usually had some other feature, such as gastrointestinal bleeding; 88 per cent of the patients had severe grade 3 or 4 symptoms.

Operation

A full description of the technique of the anterior gastropexy has been given elsewhere (Boerema, 1969). Essentially, it involves reduction of the stomach and lower oesophagus into the abdomen aided by freeing of the vagi and the oesophagus from all surrounding structures by blunt dissection. Approximation of the two limbs of the right crus behind the oesophagus is optional. The gastropexy itself consists of approximating the anterior wall of the stomach 0·5 cm below the lesser curve to the linea alba using five or six nonabsorbable sutures. The intention is to take up the slack of the lesser curve so that ultimately the intra-abdominal oesophagus and the upper part of the lesser curve feel like a very tense cord extending from the hiatus close along the undersurface of the liver to the anterior abdominal wall 2·5 cm to the right of the midline.

Results

Mortality

Three patients died in the immediate postoperative period. These deaths were due to myocardial infarction in a man aged 59, pulmonary embolus in a man aged 83 and a combination of bronchopneumonia, subphrenic abscess and wound dehiscence in a man aged 64. The latter patient had undergone an operation for repair of hiatus hernia 5 years previously, and during the mobilization prior to performing the gastropexy his oesophagus was torn and resutured. This was the only immediate postoperative death that could be attributed to the nature of this operation rather than to the hazards of surgery and anaesthesia in general. However, the 3 deaths together give a perioperative mortality of 4·4 per cent. A further patient died

* At time of survey, therefore including patients at various postoperative intervals.

6 months after the original operation, the cause of death being bronchopneumonia and upper gastrointestinal haemorrhage following oesophagoscopy and insertion of a Celestin tube for oesophageal stricture. It was felt at the second operation that the stricture may have been neoplastic, but no biopsy was taken and post-mortem examination was not performed. Her case was included in the analysis at 0–6 months, as she was seen 5 months postoperatively with grade 3 dysphagia. A fifth patient died of causes unrelated to her hiatus hernia repair 12 months postoperatively.

Morbidity

It was common to get minor degrees of dysphagia for the first 4–6 weeks but this symptom nearly always disappeared spontaneously and patients could be confidently reassured on this point. Apart from the cases of pneumothorax, dysphagia and vomiting, the immediate complications (*Table VII*) were not specific to the operation. The incidence of incisional hernias is undoubtedly related to the relative weakness of a midline incision associated with wound sepsis. One patient reacted against the thread sutures and underwent several explorations of wound sinuses.

Follow-up

At the time of the review the length of follow-up ranged from less than 6 months to more than 4 years. Obviously the numbers of patients available for review decreased with a lengthening postoperative time interval. Not all the available patients were seen at each time interval as most had been discharged from the outpatients' department soon after their operation. In some cases it was possible to fill in the correct grading of symptoms from details on the *pro formas* of the previous survey (Magary, 1972). When this was not possible the grade of symptoms at a particular time interval has been extrapolated from prior or later information, the worse grading of the two possibilities being assumed. Thus, if a patient seen in the clinic between 6 and 12 months was thought to have mild grade 2 symptoms and then the next contact was through the questionnaire at 2–3 years when the patient admitted to no symptoms (grade 1), it would be assumed for this survey that for the intervening time interval of 1–2 years he would have had grade 2 rather than grade 1 symptoms.

The results of these facts and assumptions are shown in *Table VIII*. It can be seen that up to 6 months postoperatively two-thirds of patients are completely symptom-free (grade 1), but that over the years this number drops to around 40 per cent. If, however, the patients with mild grade 2 symptoms (e.g. 'mild heartburn', 'mild indigestion', 'occasional slight nausea') are grouped with those with no symptoms, the numbers stay steady at around 90 per cent. This carries with it, of course, the corollary of a 10 per cent failure rate, i.e. those with severe grade 3 or 4 symptoms. Many patients with grade 2 symptoms also wrote of their own accord that they were grateful for the improvement in their wellbeing, and that they regarded the operation as a success. Only one patient claimed to have grade 4 symptoms and she had been noted preoperatively to be an unhappy woman (probably with just cause) with a strong functional overlay.

The current state of the patients' symptoms was assessed with regard to the grading of their initial symptoms (*Table IX*). This analysis obviously involved only the 63 patients alive at the time of the survey. Six patients said they were no better off, and one claimed to be worse off than before operation.

It should be said that the surgeon operating on all these patients has not participated in the analysis of the results and so in that sense they are presented by a disinterested person.

Discussion

Boerema first performed his operation of anterior gastropexy in 1952 and several reports of his cases have appeared since then. He devised the operation as he became dissatisfied with his own high recurrence rate in hernias repaired through both the chest and the abdomen. There is difficulty, of course, in deciding what constitutes a recurrence, for about 25 per cent of the anatomically good results are no success clinically, and about 25 per cent of patients who are symptom-free show an anatomical recurrence (Boerema, 1969). In the present survey the presence or absence of symptoms has been the factor determining success or failure, for it is in these terms alone that the patient judges whether or not an operation has been worth while.

A recent historical review of surgery for hiatus hernia (Mullard, 1971) shows how early emphasis on the anatomical defect and therefore the necessity for an anatomical repair, as advocated by Harrington (1940) and Allison (1951), gave way to a more physiological approach concentrating on the prevention of gastro-oesophageal reflux. The concept of the right crus carrying responsibility for maintaining the sphincter and preventing reflux was important in this new approach (Belsey, 1954). Boerema, however, rejects this theory, finding it unlikely that prevention of gastric reflux depends upon a muscular arch not situated at the oesophagogastric junction.

In his dissatisfaction with the results of repairing hiatus hernias by narrowing the hiatus and fixing the oesophagus to the diaphragm, Boerema, initially concerned only with preventing the upward herniation of the stomach, concentrated on a third principle: fixation of the stomach from below, and attached the stomach to the best available structure—the anterior abdominal wall. He was then struck by the constant absence of reflux, the longer length of intra-abdominal oesophagus resulting from anterior gastropexy never becoming the seat of postoperative oesophagitis. He concluded that the crural sling played no part in controlling reflux and so directed his attention to the oesophagogastric junction.

He postulated that the angle formed by the long axes of the oesophagus and the lesser curve of the stomach was of paramount importance. The more nearly parallel these axes were, the less likely was it that regurgitation would occur. The mechanism responsible for maintaining this angle acute was not the fixed sling of the crura but a mobile sling formed by intrinsic gastric musculature, beginning distally on the lesser curve, ascending up the cardia, splitting to pass in front of and behind the oesophagogastric junction and rejoining in the cardiac notch. He likened this sling to a tennis racket, the head around the lower oesophagus and the handle along the lesser curve. Pulling the handle down would accentuate the oblique entrance of the oesophagus into the stomach, thus preventing reflux. Boerema maintained that the mobile sling did just this in life, pulling from the fixed point of the retroperitoneal duodenum. Attaching the lesser curve of the stomach to the anterior abdominal wall under tension would have exactly the same effect on the oesophagogastric angle and so on the prevention of reflux.

Two problems should be mentioned with respect to this survey. First, although much data was obtained from the case notes, information concerning the latest condition of the patients was obtained by means of a postal questionnaire. As always, this has problems of imprecision. The questionnaire was designed, however, to eliminate this as far as possible.

P 25 354

and one was impressed with the care with which the majority of patients filled it in. Possibly this was some reward for its brevity. Only four specific questions were asked. Space was provided for additional comments. In this way some separation of the factual from the emotional response was achieved. Secondly, in common with other authors (Zuidema, 1972) a high proportion (32 per cent in this survey) of patients had additional intra-abdominal pathology (*Table III*), most of which was dealt with at the same time as the gastropexy (*Table VI*). Again this makes for difficulties in assessing the significance of symptoms reported by the patients. This difficulty is acknowledged and has been catered for to a certain extent by asking the patients for an exact description of their symptoms. These were then assessed and categorized by the author. For example, postoperative symptoms such as heartburn and dysphagia were regarded as being associated with hiatus hernia and reflux, whereas postprandial distension after gastropexy and vagotomy seemed more likely to be due to the latter. In view of these problems, however, it is recognized that the findings of this survey should be interpreted with some caution.

In comparison with Boerema's review of 500 cases, giving a mortality rate of 1 per cent and a recurrence rate of 5 per cent (Boerema, 1969), the present survey is a modest one. Nevertheless, it has value in that it presents the results obtained by a surgeon who has learnt the technique from its originator, found that the operation works (Magary, 1972) and has therefore continued to use it. Up to now, the technique and the results obtained with it by Boerema have met with only mild interest in this country. It is felt that a greater interest is now beginning to be shown and the publication of results obtained here may encourage other surgeons to try it out, particularly if they are dissatisfied with their own results using other techniques. The main advantage of the Boerema anterior gastropexy are that it has a 90 per cent success rate and that it can be performed quickly (about 45 minutes) and safely.

Acknowledgements

I would like to thank Mr H. T. John for his permission to study the patients under his care, the patients themselves for their willingness and care in replying to the questionnaire and Miss Joan Sellick and Miss Susan Davies for invaluable secretarial assistance.

Atrophic gastritis in gastrectomy specimens

J. M. SKINNER, P. J. HEENAN AND R. WHITEHEAD*

SUMMARY

Examination of gastrectomy specimens has shown that atrophic gastritis and intestinal metaplasia are widespread and have the same distribution in cancer of the stomach as in gastric ulcer affecting the body. Their distribution is restricted to the distal part of the stomach in pyloric ulcer. After gastrojejunostomy the distribution is also like that seen in cancer. There is a close association of widespread atrophic gastritis and intestinal metaplasia with the development of cancer and a higher cancer rate after stomach operation for benign conditions. The similarity of distribution of atrophic gastritis and intestinal metaplasia in the stomach with body ulcer to that in cancer and after gastrojejunostomy points to a higher cancer risk in the stomach containing a body ulcer.

IT has been shown by Stalsberg and Taksdal (1971) that 15 years after patients have been operated on for peptic ulcer the incidence of carcinoma of the stomach is greatly increased. There is a very close relationship between the development of cancer and the presence of atrophic gastritis and intestinal metaplasia (Morson, 1955a; Siurala and Seppäla, 1960; Blackburn et al., 1968). It is equally well known that ulcers in different parts of the stomach are associated with a different distribution of gastritis and that gastritis progresses after the ulcer has been treated (Gear et al., 1971). Thus it is important to know how the extent of atrophic gastritis and intestinal metaplasia associated with gastric ulcers in different sites compares with that associated with carcinoma of the stomach and how previous surgery may alter the situation. We have therefore examined gastrectomy specimens from patients operated on for carcinoma and gastric ulcer and paid particular attention to the type and distribution of chronic gastritis and the presence of intestinal metaplasia, the site of the ulcer or cancer and any previous surgery.

Materials and methods

Stomachs from all gastrectomies performed in the Radcliffe Infirmary, Oxford, from 1970 to 1973 were examined. Gastrectomy specimens prior to 1970 were deemed unsuitable because the sampling was limited and not accurately recorded. Consequently, a prospective study was planned and the stomachs were opened along the greater curve, just anterior to the omentum, and pinned out on to a cork board before being placed into standard 10 per cent formol–saline fixative for 2 days. The position of the ulcer or tumour was noted.

Following fixation, blocks of tissue between 2·5 and 3·5 cm in length were taken as follows:

1. Along the entire lesser curve.
2. Alternate blocks along the greater curve but always including the lines of resection.
3. Two blocks from the posterior wall and two from the anterior wall of the body area of the stomach.
4. Through the ulcer or cancer if not already included in blocks 1–3.

Sections 4–5 μ in thickness were cut and stained by haemotoxylin and eosin, periodic acid-Schiff, Foot's reticulin and a modified Maxwell's method (*see* Whitehead, 1973). One case of sarcoma and one of secondary malignant melanoma were excluded. In each block the presence of superficial gastritis, atrophic gastritis and intestinal metaplasia was noted, as defined in the classification of gastritis of Whitehead (1973). No attempt was made to grade the lesions.

For the purposes of this study the pyloric region is defined as that area of stomach in the fixed specimens bounded at its lower end by the duodenal mucosa and at its upper end by a line drawn between a point 2 cm above the duodenal mucosa on the greater curve and 4 cm on the lesser curve. The pyloric region does of course vary in extent, and pseudopyloric metaplasia is often present on the lesser curve near the margins of ulcers even when they are very high. Our definition consequently is one of convenience, in order to record the information. Ulcers occurring in this zone were termed 'pyloric ulcers' and in the rest of the stomach 'body ulcers'.

Results

The results are shown in *Table I.* Atrophic gastritis and intestinal metaplasia are uncommon in pyloric ulcers and occur almost entirely in the pyloric region as defined, or in the adjacent lesser or greater curve blocks. The less severe lesion of superficial gastritis alone is also seen in the pyloric region in about half the pyloric ulcer cases. In body ulcers the distribution is more widespread and in nearly all cases was seen in all the blocks. This distribution is similar to that seen in cases of cancer.

In the cases of gastrectomy following previous gastrojejunostomy for duodenal ulcer (in 3 cases associated with stomal ulcer and 3 with pyloric ulcer) the distribution of atrophic gastritis and intestinal metaplasia is again similar to that in cancer.

Discussion

Although Stalsberg and Taksdal (1971) found that there was no correlation between the extent of gastritis and metaplasia in gastrectomy specimens

when operation was carried out for a benign condition and whether or not the patient subsequently developed cancer, they employed rather limited sampling of the specimens and did not clearly indicate the type of lesion for which the gastrectomy was carried out.

Our findings for gastritis and metaplasia in gastric ulcer and cancer are similar to those made by Magnus (1946) and Morson (1955b), but neither of these authors distinguished between pyloric and body ulcers.

Our findings also confirm those made by Gear et al. (1971) in a multiple fibre-optic biopsy study. The gastritis is widespread in association with ulcer of the body of the stomach and more localized distally in the stomach with prepyloric ulcer. Gear et al. (1971) found less intestinal metaplasia, but this is explained by the fact that it is often a patchy lesion and the bigger the sample of tissue the more likely it is to be found.

The distribution of atrophic gastritis and intestinal metaplasia associated with duodenal ulcer (Morson, 1955a) is identical to the distribution we have shown in prepyloric ulcer. This is perhaps not surprising since clinically they behave in a similar manner (Johnson, 1957). We have not been able to examine ordinary gastrectomy specimens in duodenal ulcer but we have confirmed the presence and distribution of gastritis in a fibre-optic biopsy study (Whitehead, 1974). It is of some importance that in 6 cases of duodenal ulcer treated by gastrojejunostomy and subsequent gastrectomy for recurrent ulcers (stomal 3 and pyloric 3) the stomach had a pattern of gastritis comparable to that seen in body ulcer. This distribution is the same as that seen in cancer of the stomach. It has been designated type B gastritis (Strickland and Mackay, 1973) to distinguish it from type A, i.e. that which is associated with pernicious anaemia. There is considerable evidence that type B gastritis precedes carcinoma (Siurala and Seppälä, 1960; Siurala et al., 1966; Imai et al., 1971; Walker et al., 1971). There is every indication, therefore, that patients with gastric ulcer in the body are more cancer-prone than those with ulcer in the pylorus or duodenum.

Whilst surgery in the treatment of peptic ulcer obviously has an established place it would appear that there is room for the investigation of methods of treatment of duodenal and pyloric ulcers which would obviate the change into 'cancer' pattern gastritis after operation. Gastro-enterostomy operations seem to be particularly prone to cause widespread atrophic gastritis and intestinal metaplasia (Kobayashi et al., 1970) and our findings support this. Operations which conserve the anatomy of the stomach, e.g. highly selective vagotomy, may prove to have a less deleterious effect in terms of subsequent gastritis. As far as body ulcers are concerned, there is a case in ideal circumstances for careful periodic follow-up by endoscopy and biopsy following operation.

A clinicopathological review of 68 carcinomas of the gallbladder

L. A. DONALDSON AND A. BUSUTTIL*

SUMMARY

A clinical and pathological review of 68 patients with a primary carcinoma of the gallbladder was undertaken. A prolonged preceding history of biliary disease was noted. Preoperative radiological and biochemical investigations were not helpful, but an isolated elevation in serum alkaline phosphatase level in the absence of any biliary obstruction or hepatic dysfunction was noticed in some patients. The significance of stones in relation to pathogenesis is discussed. A more radical surgical approach involving a partial hepatectomy appears to be the only possible treatment in view of the mode of spread of this tumour and the bad overall prognosis.

IN general surgical practice the incidence of tumours of the gallbladder is often considered negligible, yet Chandler and Fletcher (1963) noted that it accounts for about one-fifth of all carcinomas of the gastrointestinal tract. Graham (1931) has shown that it represents 8–10 per cent of all malignant disease in women, and Arminski (1949) found it occurring in 4·5 per cent of all cancer autopsies; Cooke et al. (1953) believed it to account for about 1 per cent of all carcinomas in Britain. Ross and Hickok (1960) reported that 7 per cent of all surgically removed gallbladders in patients over 70 years of age contain a primary malignant growth, and Horwitz and Rosenweig (1960) suggested an incidence of 6 per cent in patients over 50 years. Despite its reported frequency, the diagnosis and treatment of tumours of this site are surrounded by an aura of utter despondency and hopelessness (Leading Article, 1971).

A study of this problem was undertaken by reviewing all the patients in whom such a diagnosis was established in the Western and Victoria Infirmaries in Glasgow between the years 1961 and 1973 inclusive. A total of 68 cases was collected from the routine histopathological and autopsy records; 4361 intact gallbladders and gallbladder biopsies were submitted for histological examination and the incidence of carcinoma in them was 1·2 per cent (53 cases). Over this same time interval 10 748 autopsies were carried out in which there were 27 histologically confirmed cases (namely 0·25 per cent of the total examinations). Twelve of our cases were diagnosed initially at laparotomy and subsequently came to autopsy examination. During this same period the incidence of gallstones in autopsy examinations was also recorded (*Table I*).

Table I: INCIDENCE OF GALLBLADDER CALCULI IN 10 748 AUTOPSIES

Age (yr)	Sex (% patients) Male	Female
<60	3·4	10
60–64	7	14
65–69	11	25
70–74	13	27
75–79	20	35
[illegible]80	22	35

Presenting symptoms and signs

On admission 51 of the patients had symptoms and signs of an acute on chronic cholecystitis; 18 were also jaundiced and 25 had a palpable right hypochondrial mass (*Table II*). Eight other patients presented with painless jaundice and the findings at clinical examination were unremarkable. Another 3 patients complained of vague generalized dull abdominal pain alone, but on examination a tender mass was palpable in 1 patient, and in another in whom upper abdominal tenderness was detectable the diagnosis was made at laparotomy. The remaining 6 cases were diagnosed solely at necropsy examination and biliary symptoms had not been recorded during life.

Table II: PRESENTING SYMPTOMS AND SIGNS IN 68 PATIENTS

Symptom	No. of cases	Right hypochondrial mass
Biliary dyspepsia	33	14
Biliary dyspepsia and jaundice	18	11
Painless jaundice	8	0
Generalized abdominal pain	3	1
No biliary symptoms, diagnosed at autopsy	6	0

In 1 of the latter patients death was due to disseminated malignancy, but in the other cases the carcinoma was an incidental finding and not a direct cause of death. The duration of gallbladder dysfunction exceeded 1 year in 25 patients (*Fig.* 1). This history was substantiated in 5 patients by the occurrence of a cholecystostomy with removal of calculi over 15 years previously, and in 9 other patients by a record of a nonfunctioning gallbladder observed during cholecystograms carried out during former hospital attendance many years previously. Concomitant maturity-onset diabetes mellitus was known to be present in 6 patients. Weight loss was not a prominent feature even in the advanced cases.

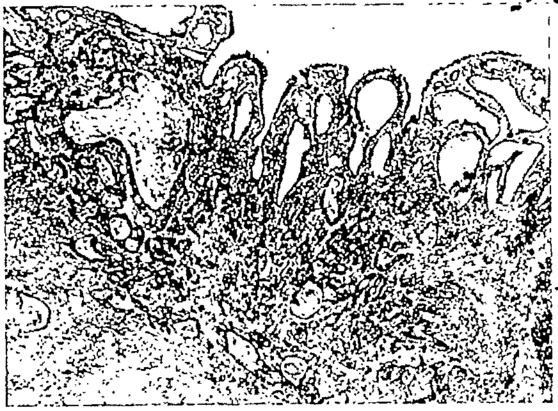

Fig. 3. Primary adenocarcinoma of the gallbladder. (× 175.)

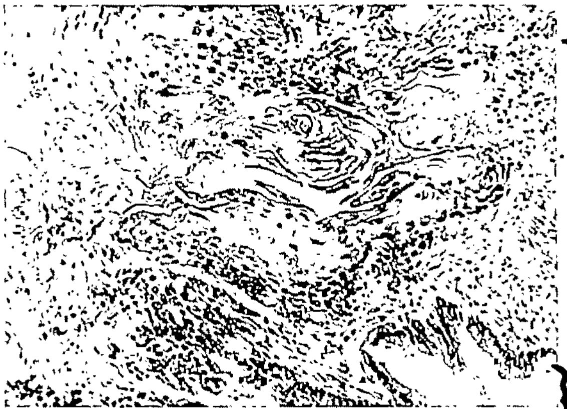

Fig. 4. Primary keratinizing squamous cell carcinoma of the gallbladder. (× 175.)

Thirty-seven patients underwent radiological investigation (*Table III*). In none of these cases was a carcinoma of the gallbladder diagnosed and in all the patients undergoing a cholecystogram a nonfunctioning gallbladder was found. In 2 of the 7 patients undergoing barium studies the findings suggested a gastric carcinoma.

Preoperative biochemical tests of hepatic function were available in 35 patients (*Table IV*). The only finding of note was an elevation of serum alkaline phosphatase in conjunction with a normal serum bilirubin and normal transaminases (aminotransferases) in 10 cases. In these patients there was no overt evidence of metabolic bone disease.

Fifty-three patients were subjected to a laparotomy and in 14 of them a cholecystectomy was performed (*Table V*). Although no clinical suspicion of malignancy was entertained, in 10 of the latter patients, on reviewing the surgeon's notes, the operative procedure was considered 'difficult' as multiple adhesions bound down the gallbladder to the liver. In the other 4 cases the suspicion of malignancy was raised at the actual time of the operation and subsequently confirmed histologically. In the remaining 39 patients dissemination of the carcinoma prevented any definitive or palliative procedures, although 6 of the

Total	53	28	9	4	6	6

Three patients survived for longer than 3 years; the longest survival was 8 years.
N/A, No information available.

Pathology

Histological examination showed that 74 per cent of all the tumours were adenocarcinomas of varying differentiation; squamous cell carcinoma and anaplastic carcinoma accounted for 4·4 and 11·6 per cent respectively (*Figs.* 3, 4). In one autopsy a primary spindle cell sarcoma was discovered. In the remaining 6 cases the histological type was not specified.

Gallstones were present in addition to the tumour in 47 cases (70 per cent). Forty-five had multiple faceted stones and the other 2 were cholesterol in type. No information was available for the other 9 cases.

In order to assess the prognosis in the cases that underwent surgery, staging was attempted according to the extent of spread of the tumour (*Table VI*). In 22 cases the carcinoma either was limited solely to the gallbladder (12 cases) or had spread to involve the cystic lymph node and the other nodes in the immediate vicinity of the cystic and common bile ducts (10 cases). Spread to the right lobe of the liver had already occurred in the remaining cases. However, in 17 of these patients the spread was limited to the gallbladder bed with minimal superficial infiltration of hepatic parenchyma. Local spread to the colon had occurred in 1 case and in 3 other cases there was generalized peritoneal spread. The pattern of spread in the autopsy cases confirmed the impression at operation: this tumour spreads mainly by local infiltration into the right lobe of the liver and through the lymphatics to the nodes along the common bile duct. Vascular dissemination to the lungs (6 cases), lumbar spine (2 cases) and heart (1 case) was also recorded.

In none of the patients were any radical operative procedures attempted and the only survivors for longer than 6 months were those in whom the tumour was an incidental histological finding in a cholecystectomy specimen.

Discussion

There have been many reviews in the American literature of carcinoma of the gallbladder (Arminski, 1949; Gerst, 1961; Chandler and Fletcher, 1963; Holmes and Mark, 1971; Keill and De Weese, 1973), but very few have been documented in Great Britain (Illingworth, 1935; Solan and Jackson, 1971).

In the 57 cases collected by Solan and Jackson (1971) the female to male ratio was 2·6 : 1; likewise in the Swedish series of 58 cases documented by Hafström et al. (1973). In the 132 cases of Gerst (1961) the ratio was 3 : 1, and this also was shown in the cumulative review of 1061 cases for the years 1948–58 undertaken by Strauch (1960). These results concur with the fourfold higher incidence of this tumour in females noted in the present series.

There has been no significant variation of the age distribution between the sexes in this and other series (Solan and Jackson, 1971; Hafström et al., 1973), although it tends to present about 5 years earlier in male patients. This finding differs marginally from the experiences of Bossart et al. (1962), who in a survey of 76 cases found the disease occurring 10 years earlier in females.

Usually this tumour is discovered unsuspectedly at a laparotomy with a view to biliary surgery and in most series there is a low incidence of preoperative diagnosis. In the cumulative review of Strauch (1960) there were 482 gallbladder carcinomas in 34 242 biliary tract operations, representing an incidence of 1·4 per cent; Marcial-Rojas and Medina (1961) found this malignancy in 1·3 per cent of 2813 surgically removed gallbladders. In contrast, Holmes and Mark (1971) encountered 22 carcinomas of the gallbladder during 1816 cholecystectomies, an incidence of 1·21 per cent. In addition, in a further 38 patients undergoing a cholecystostomy 22 additional primary carcinomas were diagnosed, giving an incidence of 2·35 per cent in 1854 operations on the biliary tree. Keill and De Weese (1973) treated 33 patients with a primary gallbladder malignancy between 1957 and 1971 and during that time 1404 cholecystectomies were also performed; their stated incidence of 2·35 per cent is unusually elevated, but only 13 of their patients were actually submitted to a cholecystectomy.

Carcinoma was present in 0·32 per cent of the surgically removed gallbladders in this series. Bossart et al. (1962) found an incidence of 0·82 per cent; similarly Magee and MacDuffee (1968) and Seltzer et al. (1970) found the occurrence of carcinoma to be 1·1 and 0·6 per cent respectively, when each reviewed over 1000 cholecystectomies in an assessment of the postoperative mortality and morbidity. Thus it is apparent that an accurate estimate of the true incidence of this tumour proves very difficult, but it seems to be lower in Britain.

In this review the incidence of carcinoma of the gallbladder found at autopsy was 0·25 per cent. This is similar to the finding of Illingworth (1935) of 0·42 per cent, of Arminski (1949) of 0·43 per cent and of Marcial-Rojas and Medina (1961) of 0·18 per cent.

Although in most cases at autopsy or laparotomy the tumour can be confidently localized to the gallbladder as the site of origin, in a proportion of surgical cases the spread is already so extensive that only guarded speculation as to a possible origin within the biliary tract is possible. Even after a detailed dissection at autopsy the site of origin may still be difficult to determine, as multifocal carcinomas affecting the walls of the gallbladder and bile ducts simultaneously are on record (Willis, 1942).

A striking feature of the current series is the occurrence of longstanding biliary disease, which was proved in 33 patients radiologically and/or surgically; in some cases this was recorded several years prior to the final admission and diagnosis of the carcinoma (*Fig.* 1). Twenty-five (50 per cent) of our patients complained of biliary symptoms for longer than 1 year and 15 patients had symptoms exceeding 4 years. A shorter duration of biliary history was noted by Holmes and Mark (1971), who found that in only 28 per cent of their patients had there been symptoms for longer than a year. Thirty-nine per cent of the patients reviewed by Keill and De Weese (1973) had symptoms for longer than 2 years, and half of the cases reviewed by Marcial-Rojas and Medina (1961) had such complaints for between 6 months and 10 years. There was a very variable duration of biliary history in the cumulative review by Strauch (1960). Two-thirds of the 22 patients studied by McLaughlin (1964) and half of the patients reviewed by Glenn and Hays (1954) had biliary symptoms lasting for longer than 1 year. Both Illingworth (1935) (50 cases) and Horwitz and Rosenweig (1960) (20 cases) remarked about the very prolonged antecedent biliary history in some of their patients. However, Solan and Jackson (1971) found that only 13 per cent of their patients gave any previous history of biliary disease. These wide variations in the duration of preceding biliary symptoms may be due in part to the failure of recall by the patient; a number of patients in our series failed to recollect any previous biliary trouble in spite of having undergone a cholecystostomy or a cholecystogram in the past.

Robertson and Carlisle (1967) and Holmes and Mark (1971) noted that the most frequent symptom complex was indistinguishable from 'benign' biliary disease. In contrast, Strauch (1960) considered that most patients could pinpoint the transformation of a 'benign' to a 'malignant' lesion to within a week of its occurrence; Horwitz and Rosenweig (1960) remarked that a change in the pattern of pain was frequently the reason why their patients sought medical attention, the character of the pain changing to a persisting, severe, unremitting type. This feature was not confirmed in other series (Marcial-Rojas and Medina, 1961; Keill and De Weese, 1973) or in this series.

The typical cachectic and emaciated picture of a malignancy was not part of our clinical experience and even the tumours that had disseminated widely via the bloodstream failed to produce significant weight loss. Obesity prior to the development of the tumour may account for this finding and most of our patients coming to autopsy were obese.

The unhelpful (or misleading) radiological findings noted (*Table III*) are essentially similar to those of Chandler and Fletcher (1963), Solan and Jackson (1971) and Keill and De Weese (1973). Thirty-seven of our patients underwent radiological investigation of the abdomen, and calcified biliary calculi were noted in 8 cases. This is a marginally high incidence (21 per cent) when compared with the findings of Sherlock (1968), who stated that only 10 per cent of gallstones are radio-opaque. In 22 per cent of totally calcified gallbladders—the so-called 'porcelain gallbladder'—a malignancy was revealed (Polk, 1966); in the only case of this type seen at the Western Infirmary during the past 10 years there was no evidence of malignancy (Busuttil and McLean, 1974). Dystrophic calcification of the gallbladder wall is probably an indication of the duration of the biliary dysfunction, and this adds weight to the argument that prolonged biliary dysfunction may predispose to carcinomatous change (Cornell and Clarke, 1959).

The deposition of sufficient calcium salts within gallstones as to make them radio-opaque may have a similar significance.

Of the biochemical investigations of liver function available in 35 cases (*Table IV*), the serum alkaline phosphatase (SAP) estimation was the most rewarding. As expected, in cases with partial or complete extrahepatic occlusion of the common bile duct the level of the SAP invariably exceeded 30 King-Armstrong (KA) units/100 ml. However, it was also noted that in 10 cases (28 per cent of the patients with known liver function tests) there was an elevated SAP (in 1 case to 65 KA/100 ml) without any evidence of biliary obstruction at that time. Solan and Jackson (1971) also noted this finding in 8 of their 10 anicteric patients, and Hafström et al. (1973) in 8 of their 48 cases biochemically investigated. Other series have commented on the elevated SAP (Chandler and Fletcher, 1963; Hardy and Volk, 1970), but do not give any indication as to the proportion of the patients in which this was an isolated biochemical abnormality. Although these figures are small, there is a suggestion that an isolated elevation of the SAP taken in conjunction with a history of prolonged biliary dyspepsia might acquire a sinister significance. Sherlock (1968) has shown that this is a feature of early intrahepatic cholestasis; in all of our 10 patients with isolated SAP elevations there was involvement of the hepatic gallbladder bed to a variable degree.

The manner in which the 68 tumours in this series disseminated confirms previously documented experiences (Cooper, 1937; Arminksi, 1949; Fahim et al., 1962; Hafström et al., 1973). The tumour spreads locally and by lymphatics much earlier than by the bloodstream. Fahim et al. (1962), in a detailed discussion of the lymphatic drainage of the gallbladder, have shown that its lymphatic channels lead to the cystic lymph node and from there to the pericholedochal nodes on the right side of the common bile duct which in turn drain into the pancreatoduodenal and para-aortic nodes. The lymph nodes in the porta hepatis along the hepatic artery do not drain the gallbladder but only the left lobe of the liver. The nodes along the common bile duct are capable of a degree of enlargement sufficient to cause obstructive jaundice, while the liver and the more distal lymphatics are spared completely. An erroneous impression of unresectability at laparotomy was proved to be incorrect at autopsy in some of our early postoperative deaths.

Usually the presence of hepatic metastasis in a patient with an intra-abdominal tumour is considered to be a sign of advanced malignancy as such spread is assumed to be haematogenous in nature. However, the close proximity of the gallbladder to the hepatic parenchyma lends itself to relatively early direct spread to the liver without vascular involvement having occurred. The liver bed possibly becomes involved at an even earlier stage than the lymph nodes (Hafström et al., 1973). Seventeen of our cases coming to autopsy showed that the liver was involved only in the immediate vicinity of the gallbladder; more distal portions of the liver and the lymphatics were spared.

In view of this preferential mode of spread and the poor outlook in untreated cases (Strauch, 1960; Solan and Jackson, 1971) the prospects of a partial hepatic resection as part of a more radical approach to the tumour are worth consideration. Advances in surgical techniques, liver anatomy and pre- and postoperative hepatic pathophysiology have made such elective major hepatic resections for primary and metastatic tumour entirely possible (Foster, 1970). However, Glenn and Hays (1954) considered that only 20 per cent of their patients were suitable for their 'radical cholecystectomy' involving a resection of the gallbladder's liver bed, the peritoneum and retroperitoneal tissues of the gastrohepatic and pericholedochal areas. Fahim et al. (1962) observed that of their 20 patients who had undergone cholecystectomy and liver resection, 18 were dead within 18 months with only 1 patient surviving for 5 years; Brasfield (1961) reported a single case who was alive and well 5 years after having undergone similar surgery. Although Fahim et al. (1963) have stated that on anatomical and pathological grounds the treatment of early stage gallbladder carcinoma should be a cholecystectomy with wedge resection of the liver and a local nodal dissection, and in more advanced cases a right hepatic lobectomy, these procedures have been adopted only very infrequently. In Foster's (1970) review of 14 cases, though no prolonged survival was observed, there was absence of any residual tumour months and years postoperatively.

Recurrent cholecystitis and gallstones have been inculpated over the years with a causative role in primary gallbladder carcinoma (Arminski, 1949; Strauch, 1960; Marcial-Rojas and Medina, 1961; Holmes and Mark, 1971). In positive support of this, carcinomatous change of the gallbladder's epithelium has been induced through the introduction of methylcholanthrene pellets into the gallbladder of experimental animals (Fortner, 1955; Fortner and LeHall, 1961). However, in a review of this experimental evidence by Willis (1967) the production of such tumours seems to be species-specific and not easily reproducible. Burrows's (1933) review of the earlier experimental work also showed that although a 'polypoidal cholecystitis' had been produced no clearly malignant lesions were encountered. Furthermore, it is generally agreed that gallbladders exhibiting a primary malignancy almost invariably contain calculi as well. However, a third of the patients reviewed by Arminski (1949) and Strauch (1960) did not have concomitant cholelithiasis.

Gallstones are not uncommon incidental findings at necropsy, and in our own autopsy series (*Table I*) the overall incidence was 14 per cent and the occurrence in patients over 60 years of age was 18 per cent. Similarly, Cleland (1953) found an overall incidence of 8 per cent in 7000 consecutive autopsies, and Marcial-Rojas and Medina (1961) an incidence of 10·2 per cent in 1100 autopsies. The association of carcinoma with cholelithiasis also may be purely accidental.

Arminski (1949) postulated an irritative role for calculi which over the years resulted in recurrent ulcerative inflammation, reparative proliferation and regenerative hyperplasia with the eventual supervention of neoplasia, but mucosal hyperplasia and dysplasia are rare histopathological features in cholelithiasis. In the present series 7 per cent of the cases produced an antecedent history of cholecystostomy which suggested longstanding biliary tract infection and dysfunction; this was also noted in some of the series reviewed by Arminski (1949) and sporadically in other series (Keill and De Weese, 1973). However, Lund's (1960) long term follow-up of 526 patients with abnormal cholecystograms and that of Wenckert and Robertson (1966) of 781 similar patients revealed only 8 primary carcinomas of the gallbladder and these were in patients with non-functioning gallbladders.

In most series about 3 per cent of all primary carcinomas of the gallbladder are squamous in type which suggests an origin from metaplastic epithelial foci. This tumour is also commoner in females, who also have a higher incidence of calculi. Gallstones predispose to recurrent bacterial cholecystitis often due to coliform organisms, the incidence of positive culture of bile increasing with the age of the patient (Pyrtek and Bartus, 1967; Mason, 1968). Within the large intestine, coliform organisms have been shown capable of degradation of bile salts to carcinogenic agents (Aries et al., 1969); these organisms may possibly play a similar role within the gallbladder.

Acknowledgements

We gratefully acknowledge the co-operation of our surgical colleagues at the Western Infirmary and the Victoria Infirmary, Glasgow, and that of Dr J. Craik, Consultant Pathologist, Victoria Infirmary. We thank Professor J. R. Anderson and Dr R. N. MacSween for their criticism and help with this review.

Primary carcinoma of the gallbladder

A. T. M. PRAKASH, LALIT K. SHARMA AND P. N. PANDIT*

SUMMARY.
The clinical and pathological features of 100 consecutive cases of primary carcinoma of the gallbladder, treated by a single surgical unit, are described. Females outnumbered males by 2 to 1. The maximum incidence was seen in the fifth decade. Pain and the presence of a mass were the two most common clinical features. Gallstones coexisted in 45 per cent of cases. Ancillary investigations were of little value in preoperative diagnosis. At laparotomy biopsy alone was possible in a large number of cases owing to the advanced disease process. Two patients were alive 5 years after surgery. Prophylactic cholecystectomy for all diseased gallbladders, whether symptomatic or not, is advocated.

EVER since the first review of 100 cases of carcinoma of the gallbladder by Musser (1889), there has been little change in the outlook and survival rate of patients with this disease. The signs and symptoms of a resectable carcinoma of the gallbladder are similar to those of chronic cholecystitis and cholelithiasis. Persistent right upper quadrant pain, a hard gallbladder lump, jaundice and weight loss often suggest the diagnosis, but by then the disease is invariably inoperable. A 5-year survival is rare, unless an early lesion is found coincidentally in a gallbladder removed for chronic cholecystitis and cholelithiasis.

There are very few reports in the literature of a series of 100 or more cases of carcinoma of the gallbladder treated by a single team and particularly from India. The present article gives the experience of 100 cases of histologically proved carcinoma of the gallbladder, treated in the Professorial Unit of the All India Institute of Medical Sciences Hospital, New Delhi, over a period of 15 years from 1959.

Age and sex incidence

There were 68 females and 32 males, giving a female to male ratio of 2 : 1. The ages of the patients ranged from 30 to 75 years, the average being 49 years; the majority of patients, however, were between 40 and 50 years (*Fig.* 1).

Clinical features

A history suggestive of chronic cholecystitis of long duration was available in only 12 cases. Surprisingly, the average duration of symptoms in most patients was only 8 weeks.

Ninety-five patients complained of pain, often severe, usually in the epigastrium or right hypochondrium (*Fig.* 2). In the majority, it was a continuous ache. Less than 10 per cent of cases had colicky pain, with or without radiation. Seventy-five patients had marked anorexia and 70 of them had a significant weight loss. Nearly a quarter of the patients (24) complained of low grade fever. Seven patients presented with obstruction: 4 at the pylorus and 3 in the small bowel. None of these cases presented as acute cholecystitis.

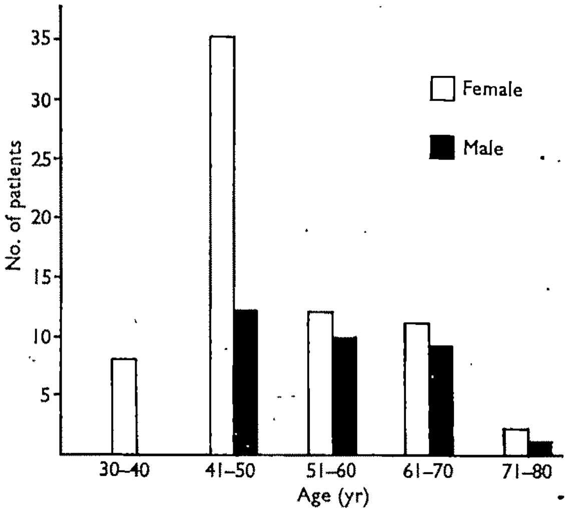

Fig. 1. Age and sex incidence.

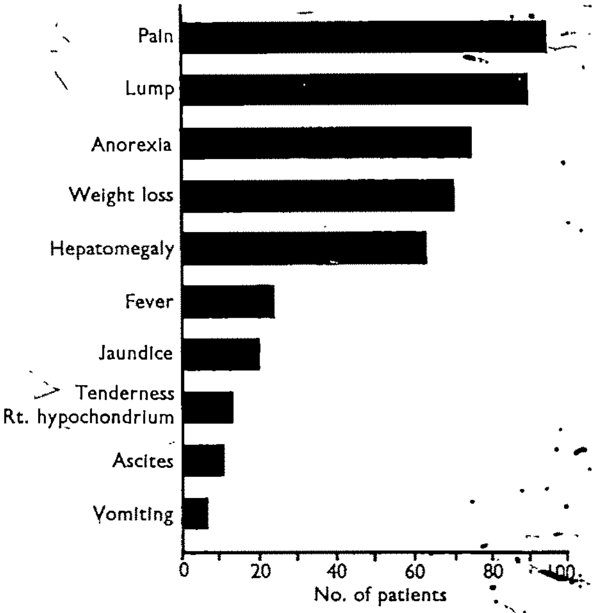

Fig. 2. Clinical features.

---

* Department of Surgery, All India Institute of Medical Sciences, New Delhi 110016, India.

In 92 cases there was a lump in the right hypochondrium which was often hard and irregular; 15 patients complained of pain over the lump. Hepatomegaly was present in 65 per cent and jaundice on admission was seen in 20 per cent of the patients. Ascites and tenderness under the right costal margin were less common.

Investigations

Radiology was of little help in diagnosis. Plain X-ray of the abdomen revealed radio-opaque calculi in only 8 cases. Oral cholecystography was carried out in 60 of the non-jaundiced patients, including 4 of those showing calculi on plain X-ray; in 2 patients only, was the gallbladder visualized faintly, and not at all in the remainder. A neoplastic filling defect in the gallbladder was never seen. In about half of the cases where an oral cholecystogram did not outline the gallbladder intravenous cholangiography was undertaken, but did not provide any additional information. Percutaneous transhepatic cholangiography was attempted in 10 of the 20 jaundiced patients; it failed in 2, the obstruction at the porta hepatis was seen in 6 and obstruction of the common hepatic duct in 2. These findings were confirmed at operation.

Routine chest X-ray revealed secondaries in the lungs in 2 cases. Barium meal, barium enema and intravenous pyelography were done when indicated. Barium meal examinations showed extrinsic pressure on the duodenum in 6 cases. Barium enema studies showed evidence of extrinsic pressure on the hepatic flexure on 3 occasions. Intravenous pyelography, done in 3 patients, did not contribute further information.

Biochemical investigations were of little assistance. The liver function tests were diagnostic of obstructive jaundice. However, in the absence of icterus, the serum alkaline phosphatase was elevated in about 25 per cent of the cases.

Association with gallstones

Gallstones were present in 45 patients. However, this may not represent the true number as in a majority of the inoperable cases a biopsy alone was done and the gallbladder was not opened.

Gross pathology (*Table I*)

The growth involved the gallbladder diffusely in 78 cases, it was in the fundus in 12 cases and the neck of the gallbladder was involved in 8 cases; Hartmann's pouch and the cystic duct were involved in 2 cases. In almost 75 per cent of the cases the tumour had infiltrated into the adjacent liver tissue.

Histology

Histologically, 90 per cent of the tumours were adenocarcinoma. Two were colloid carcinoma, 4 squamous cell carcinoma and 4 undifferentiated tumour.

Treatment (*Table II*)

Table I: GROSS PATHOLOGY

Site:	No. of cases:
Diffuse growth	78
Fundus	12
Neck	8
Hartmann's pouch	1
Cystic duct	1

Table II: OPERATIONS PERFORMED

Operation:	No. of cases:
Cholecystectomy	20
Cholecystectomy with wedge resection of liver	12
Cholecystectomy with resection of hepatic flexure	6
Biliary/intestinal short circuiting	10
Diagnostic laparotomy and biopsy	52

Cholecystectomy alone or with hepatic wedge resection was performed in 32 cases. Segmental resection of the hepatic flexure of the colon was an added procedure in 6 cases. Bypass procedures were done in 10 patients; 6 of these were for gastrointestinal obstruction and 4 for biliary obstruction. In the remainder the disease was too far advanced for any major surgical procedure; in these patients biopsy alone could be done from the gallbladder, liver, lymph nodes or omentum.

Survival

Twelve patients died within 1 month of the operation. Biliary peritonitis, hepatic coma and wound dehiscence were the main causes of death. Gastric dilatation was the cause of death in 1 patient. The cause of death was not known in 2 patients. Only 15 patients were alive 1 year after operation and 3 were alive after 3 years. The average survival time for the patients after operation was 6 months. Thus, the overall prognosis is gloomy. Two patients are alive 5 years after a 'curative' excision.

Discussion

The incidence of primary carcinoma of the gallbladder varies widely in different reports. In Britain less than 1 per cent of carcinomas arise in the gallbladder (Solan and Jackson, 1971). The condition appears to be more common in the United States (Holmes and Mark, 1971; Pemberton et al., 1971). In contrast, owing to the lack of a cancer registry, the actual incidence of carcinoma of gallbladder in India is subject to a variety of opinions. However, this series of 100 histologically proved cases over a period of 15 years from a single surgical unit indicates that the disease is not uncommon in India.

Almost all reports suggest that gallbladder carcinoma is predominantly a disease of middle-aged or elderly women. The female to male ratio of 2 : 1 in this series is typical. There are only one or two reports in the literature stating that the disease is more common in men (D'Aunoy et al., 1938), and these reports relate to small series.

The average age of 49 years in this series is lower than that mentioned in Western literature (Holmes and Mark, 1971; Solan and Jackson, 1971). Most of our patients were in the 40–50 age group. There was no sex difference in age incidence. The youngest patient in this series was a female aged 30 years. However, Rudolph and Cohen (1972) reported carcinoma of the gallbladder in an 11-year-old Navajo girl, this being the youngest patient reported so far.

The aetiology of carcinoma of gallbladder is not clear. Chronic infection, gallstones and benign neoplasms have been mentioned. The incidence of gallstones in association with carcinoma of the gallbladder varies from 54 to 100 per cent (Strauch and Providence, 1960; McLaughlin, 1964). Hart et al. (1971) stated that cholelithiasis plays a major part in the aetiology of gallbladder cancer. Comfort et al. (1948) could not find carcinoma of the gallbladder in 112 cases of asymptomatic biliary calculi followed over a period of 10–25 years. Warren and Blach (1940) reported that 2·5 per cent of patients of cholelithiasis would eventually develop carcinoma. In our series gallstones were present in 45 per cent of the cases. However, this may not represent the true figure, as in a large number of cases biopsy alone was obtained. A combination of factors such as chronic mechanical irritation, infection, local metabolic dysfunction, bile stasis and individual host susceptibility may play a role in the development of carcinoma of the gallbladder (Strauch and Providence, 1960; Solan and Jackson, 1971).

The clinical picture of carcinoma of the gallbladder is non-specific. A low clinical diagnosis rate is common in almost all reported series. This is accounted for by the indefinite symptoms and signs and the lack of help from ancillary investigations.

Gallbladder carcinoma is asymptomatic in its early and potentially curable stage. The clinical features in our patients were typical of late presentation. Pain in the epigastrium or right hypochondrium, anorexia, weight loss and low grade fever were the common symptoms. A right upper quadrant mass, hepatomegaly and jaundice were the most common physical signs. These clinical features have also been seen in the majority of cases reported in the literature. Solan and Jackson (1971) commented on the frequent history of long-standing biliary disease in association with gallbladder cancer, but this occurred in only 12 per cent of our cases.

Ancillary investigations are of little help in diagnosis. Anaemia, jaundice and disturbed liver functions are non-specific findings. Plain X-ray of the abdomen showed radio-opaque calculi in only 8 cases. Cholecystography, both oral and intravenous, usually showed a non-functioning gallbladder. A filling defect due to a neoplasm, as described by Samuel (1966), was never seen. Percutaneous transhepatic cholangiography can be a useful aid in jaundiced patients to decide the level and nature of the obstruction and to assess operability (Machado, 1971). Selective angiography has also been used by some workers, but its efficacy has yet to be established (Sato et al., 1969).

Adenocarcinoma is the commonest type of gallbladder carcinoma. This was confirmed in our series, followed by squamous cell, colloid and undifferentiated tumours. An almost similar incidence has been reported by other authors (Strauch and Providence, 1960). However, Litwin (1967) reported a higher number of undifferentiated carcinomas. The rare tumours like carcinoid, melanoma (Gradisar and Kelly, 1970) and angiosarcoma (Tanga and Ewing, 1970) were not seen in our series.

In the majority of our cases, only a diagnostic laparotomy and biopsy were possible. Several authors reported a similar experience (Litwin, 1967; Robertson and Carlisle, 1967; Solan and Jackson, 1971). Despite a fairly large number of curative excisions, only 2 patients lived for 5 years. One of them was operated upon for benign gallbladder disease and carcinoma was an incidental finding.

Uniformly bad prognosis has also been the experience of other workers. In the collective review published by Strauch and Providence (1960) the 5-year survival rate was 1 per cent out of a total of 1061 cases. No large series has reported a higher than 6 per cent 5-year survival rate.

The dismal outlook in gallbladder carcinoma is attributed mainly to three factors: elderly patients, early spread to the liver and lack of specific clinical features (Chandler and Fletcher, 1963). Fahim et al. (1962) described in detail the modes of spread of carcinoma of the gallbladder. Based on this and on our own experience, we tend to agree with Appleman et al. (1963) that radical surgery has a very limited role to play in improving the overall prognosis of gallbladder carcinoma.

Since early diagnosis is almost impossible and improvement of surgical technique has not altered the prognosis, the only way one can perhaps improve this dismal outlook is to emphasize prophylaxis.

Prophylactic cholecystectomy in cases of asymptomatic gallstones has been suggested on the grounds that it may prevent future cancer (Nield, 1964; Hart et al., 1971; Holmes and Mark, 1971). There are others who disagree with this contention (Solan and Jackson, 1971). Although there is no convincing proof that gallstones are carcinogenic, we feel that early cholecystectomy should be done for all cases of cholelithiasis, whether symptomatic or asymptomatic, provided that there is no surgical contraindication.

The natural and unnatural history of pancreatic pseudocysts

S. SANKARAN AND ALEXANDER J. WALT*

SUMMARY

Experience with 131 pseudocysts of the pancreas in 112 patients has been analysed with a view to answering specific questions. Spontaneous regression was documented in 8 per cent. Complications occurred in 33·5 per cent of the pseudocysts, including obstruction of adjacent organs, rupture, haemorrhage and pancreatic ascites. In 14 pseudocysts, rupture into the gastrointestinal tract, the peritoneal cavity or the pleural cavity, when unassociated with haemorrhage, had a mortality rate of 14 per cent. Sixteen patients with significant haemorrhage associated with a pseudocyst had a mortality rate of 61 per cent; early direct surgical control is advocated. Pancreatic ascites was associated with 14·5 per cent of the pseudocysts and had a 40 per cent recurrence rate, which can be greatly diminished when operative procedures are guided by pancreatography. The mortality rate for the surgical treatment of 97 uncomplicated pseudocysts was 6 per cent and the recurrence rate was 11 per cent. The prime cause of death was haemorrhage. Seven of the 131 pseudocysts were synchronous and 12 were metachronous. The actual figure is probably higher. Small cysts of the head of the pancreas, impalpable at operation but demonstrable by pancreatography, may be the cause of severe, continuing or recurrent symptoms.

PSEUDOCYSTS of the pancreas often present many difficult clinical problems. In the past, considerable attention has been focused on the management of mature uncomplicated pseudocysts of the pancreas and satisfactory guidelines have emerged from several large studies (Warren et al., 1958, 1966; Becker et al., 1968; Rosenberg et al., 1969). Less definitive information is available on the surgical dilemmas posed by pseudocysts with complications such as rupture, haemorrhage, ascites and recurrence. Furthermore, the symptoms arising from immature and clinically impalpable pseudocysts are frequently not appreciated. With a view to refining our own approach, we have sought the answers to the following questions:

1. What is the natural history of pancreatic pseudocysts?
2. Do they regress spontaneously?
3. What are the hazards of watchful waiting for a pseudocyst to mature?
4. How is rupture of a pseudocyst best treated?
5. How is massive bleeding associated with a pseudocyst best treated?
6. What is the significance of pancreatic ascites?
7. Can symptomatic pseudocysts be impalpable even at laparotomy?
8. How often are pseudocysts multiple?

Material

The records of 112 patients with 131 pancreatic pseudocysts admitted to the Wayne State University Affiliated Hospitals (Detroit General Hospital, Allen Park V. A. Hospital and Harper Hospital) during the period 1960–72 were analysed. Twelve patients were hospitalized twice for the treatment of pancreatic pseudocysts and 7 other patients had two pseudocysts each, detected at the same laparotomy.

Seventy-five per cent of the patients were in the fourth and fifth decades. The age of the patients ranged from 16 to 79 years with a mean age of 41 years. Eighty-six patients were men and 26 patients were women.

Table I: AETIOLOGY OF PANCREATIC PSEUDOCYSTS

Aetiology	No. of patients	No. of cysts
Pancreatitis		
Alcohol	81	99*
Cholelithiasis	5	5
Alcohol+cholelithiasis	14	14
Postrenal transplantation	1	2
Pancreatic trauma	11	11
Total	112	121

* Includes 7 double cysts and 11 recurrent cysts.

Table II: SYMPTOMS AND SIGNS

Symptoms and signs	No. of admissions with symptom or sign present	Frequency in determinate cases (%)*
Pain	107	94
Nausea and vomiting	68	60
Anorexia	25	20
Weight loss (over 4·5 kg)	51	47
Diarrhoea	8	10
Fever	15	21
Mass	62	50
Tenderness	57	72
Ascites	22†	18
Jaundice	10	8
Paroxysmal hypertension	36	49

* Cases in which the finding or its absence was mentioned.
† In 3 instances ascites was due to cirrhosis.

Aetiology (*Table I*)

The development of a pseudocyst was preceded by pancreatitis (90 per cent) or pancreatic trauma (10 per cent). Alcoholism was the principal cause of pancreatitis in our patients. In none of the 19 patients with cholelithiasis was a stone detected in the common

Table III: LABORATORY AND RADIOGRAPHIC FINDINGS

Laboratory and radiographic findings	No. of admissions with test abnormal	Frequency in determinate cases (%)*
Haemoglobin <10 g/100 ml	17	23
Leucocytosis $>12\ 000/\text{mm}^3$	54	48
Serum amylase >200 Somogyi units	85	73
Serum bilirubin elevation (>2 mg/100 ml)	14	13
Carbohydrate metabolic defect	32	35
Pulmonary and/or pleural disease	27	25
Elevation of left diaphragm only	5	5
Pancreatic calcification	8	13
Mass in the region of the pancreas by:		
Upper gastro-intestinal series	89	73
Barium enema	9	36
Intravenous pyelogram	9	36
Arteriogram	7	70

* Cases in which the results of the test were available.

Table IV: LOCATION OF PSEUDOCYSTS

	Location	No. of cysts
Single cysts (105 patients)*	Head	28
	Body/tail	88
	Unknown	1
Double cysts (7 patients)	Head	2
	Body/tail	4
	Head and body/tail	8

* Twelve of these patients had recurrent cysts.

bile duct. One patient was a renal transplant recipient on steroids and azathiaprine; she was also hypercalcaemic. Eleven pseudocysts followed pancreatic trauma. Six patients gave a history of blunt trauma to the abdomen and 5 had been treated for penetrating wounds of the pancreas in the 4 months immediately preceding the development of the pseudocysts.

Symptoms and signs (*Table II*)
Most patients had pain in the upper abdomen ranging from discomfort to severe pain with or without radiation to the back. Weight loss when present was often striking and some patients had lost as much as 18 kg in 3 months. A mass was palpable in only half the cases. Twenty-two patients had chronic ascites; in 19 the ascites appeared to be due to pancreatic leakage in that the fluid contained abnormally raised amylase and protein levels, while in the remaining 3 the ascites was attributable to an associated cirrhosis of the liver. Transient hypertension was noted in 35 patients. This hypertension disappeared when the pseudocysts were adequately drained. The cause of this hypertension is unknown but may conceivably be related to the associated pancreatitis.

Laboratory and radiographic findings (*Table III*)
Twenty-three per cent of the patients were anaemic on admission; most appeared malnourished. None of these patients gave a history of haematemesis or melaena. Leucocytosis was present during the first few days of the hospital stay in 48 per cent of the patients. In many the leucocyte count fell to normal levels prior to surgical therapy. Results of culture of the pseudocyst fluid were available in 30 patients; in 5 the cultures were positive. No correlation was apparent between positive culture of the pseudocyst fluid and the presence of fever or leucocytosis or both preoperatively. The serum amylase was raised during the hospital course in only 73 per cent of determinate cases and often showed marked fluctuations. Elevated serum bilirubin levels were noted in 14 patients; in 10 the hyperbilirubinaemia could be attributed to obstruction of the common bile duct by the pseudocyst, while in 4 the jaundice seemed to be due to early cirrhosis of the liver. Pseudocysts of the head of the pancreas were sometimes associated with a raised serum alkaline phosphatase but a normal serum bilirubin. In one such patient the operative cholangiogram showed the pseudocyst greatly stretching the common bile duct and partially obstructing it (*Fig.* 1). Using as criteria for glucose intolerance a fasting blood sugar greater than 110 mg per cent, a 2-hour postprandial blood sugar over 120 mg per cent or an abnormal glucose tolerance test, 32 patients (35 per cent) demonstrated abnormalities of carbohydrate metabolism.

Radiographic studies demonstrated a mass in the region of the pancreas in only 75 per cent of the cases. In 3 patients the mass was detectable only on the intravenous pyelogram. Twenty-five per cent of the patients had unilateral or bilateral pleural effusion with or without atelectasis or pneumonia in the lower lung fields. Five others had an elevated left diaphragm as the only abnormality on the chest X-rays. Abdominal X-rays showed pancreatic calcification in 13 per cent of determinate cases; each of these patients had an abnormally raised serum amylase. Plain films of the abdomen sometimes showed non-specific ileus, ascites or findings suggestive of a mass.

Location of pseudocysts (*Table IV*)
Seven patients had two pseudocysts at the same laparotomy. In each, pancreatitis was associated with excessive alcoholic intake. Thirty-four pseudocysts (26 per cent) were located in the head of the pancreas. Twelve of these (30 per cent) caused significant obstruction of the common bile duct or duodenum. Ten patients had jaundice from obstruction of the common bile duct. The elevations in serum bilirubin were between 3 and 5 mg per cent in 4 patients, between 10 and 15 mg per cent in 2 patients and over 15 mg per cent in 3 patients. In 2 patients rupture of the cysts into the duodenum and duodenum and common bile duct respectively was demonstrated radiologically concomitant with the regression of jaundice.

Natural and unnatural history
Forty of the 131 pseudocysts either regressed spontaneously or were associated with one or more complications—rupture, haemorrhage or ascites—

before any operation was performed. Non-operative treatment was deliberately chosen in only one patient owing to her poor respiratory function from previous pulmonary tuberculosis and a thoracoplasty. The cyst in the tail of her pancreas was confirmed by a selective splenic arteriogram. For the past 1½ years she has been followed as an outpatient and has been taking simple analgesics periodically. She has abstained from alcohol and her weight has been stable at around 44 kg.

Spontaneous regression

Spontaneous regression of a pseudocyst was observed in 10 patients. In 3 of these, spontaneous drainage of the cyst into the duodenum (*Fig*. 2), duodenum and common bile duct (*Fig*. 3) and colon (*Fig*. 4) respectively was radiologically demonstrated. In another unusual

On admission	4
First week	6
Second week	7
After 4 weeks	3

patient the pseudocyst regressed and reappeared repeatedly, depending upon whether the patient was recumbent or in the upright position. In the remaining 6 patients, spontaneous regression of a pseudocyst was inferential; a mass with all the classic features of a pseudocyst, demonstrated by palpation and radiological studies, disappeared as the patient became asymptomatic.

Pseudocysts with preoperative complications

Thirty-four pseudocysts (26 per cent) in 33 patients developed one or more complications preoperatively (*Table V*). Eight patients with these complications died and 6 had a recurrence of a pseudocyst or ascites or both. In the patients whose pseudocyst (21) ruptured or bled before operation the mortality was high (*Table VI*). All 6 patients with a recurrence had pancreatic ascites preoperatively.

a. Rupture: Twenty pseudocysts in 19 patients ruptured acutely into a variety of adjacent organs and spaces (*Table VII*); 4 of these patients had associated pancreatic ascites, another 4 had associated massive haemorrhage and 2 had both ascites and massive haemorrhage. The time of rupture was unpredictable (*Table VIII*). Only one of the ruptured pseudocysts, operated on 4 weeks after rupture, had walls thick enough for internal drainage.

Seven patients had acute rupture of their pseudocyst into the peritoneal cavity with signs and symptoms of peritonitis. In one of these the rupture followed haemorrhage from the splenic artery into the pseudocyst, and in another the cyst had also eroded into the stomach. Rupture of a pseudocyst into the mediastinum and right pleural cavity occurred via the oesophageal hiatus in 2 cases and the aortic hiatus in 1. Of the 8 patients in whom pseudocysts ruptured into the gastro-intestinal tract, 4 had associated massive upper gastro-intestinal bleeding. The source of bleeding was the left gastric artery in the pseudocyst that ruptured into the oesophagus and the gastroduodenal artery in the 2 cysts that ruptured into the duodenum; in the fourth patient the bleeding ceased

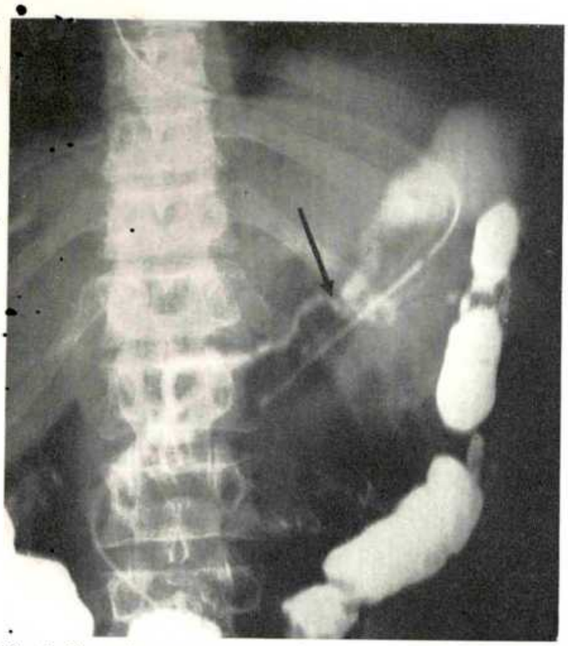

Fig. 5. Operative pancreatogram in a patient with pancreatic ascites showing leakage of contrast medium from the pancreatic duct into a pseudocyst which was leaking.

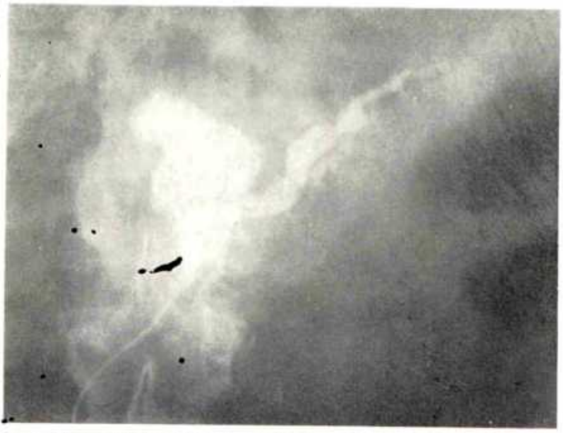

Fig. 6. Operative pancreatogram showing a pseudocyst in the head of the pancreas which has ruptured into the right pleural cavity.

of the pseudocyst preoperatively and died of sepsis, while the fourth died of massive bleeding 6 hours after cystogastrostomy. Six patients (40 per cent) had a recurrence of a pseudocyst or ascites or both. One recurrence followed laparotomy and peritoneal lavage in a patient whose pseudocyst had ruptured into the peritoneal cavity; 4 other recurrences followed external drainage alone.

Uncomplicated pseudocysts

Ninety-seven pseudocysts in 79 patients developed no preoperative complications such as ascites, rupture or haemorrhage. *Table XII* details the management and results of therapy.

Table XI: PANCREATIC ASCITES (19 CASES)

	No. of cases:

Cystogastrostomy	25	8 } 5	8 } 11
Cystojejunostomy	23	4 }	17 }
Excision and partial pancreatectomy	13	18	0
Total	97	6	11

Six patients died. One patient who was progressing satisfactorily after distal pancreatectomy and splenectomy died of massive pulmonary embolism on the eighth postoperative day. A second patient died postoperatively of renal failure after the same procedure. The remaining 4 deaths were associated with post-operative bleeding after external drainage in 1 patient, after cystogastrostomy in 2 patients and after Roux-en-Y cystojejunostomy in 1 patient. All 4 were treated non-operatively. Non-fatal complications post-operatively included prolonged pancreatitis in 2 patients, left subphrenic abscess in 1 and upper gastro-intestinal bleeding in 1 which ceased spontaneously after transfusion of 7 units of blood.

From *Table XI* it will be noted that 2 patients had transduodenal aspiration of the cyst only. The capacity of these two cysts was only 10 and 30 ml respectively. Both had severe and persistent symptoms and slight widening of the duodenal sweep on upper gastro-intestinal radiographic series, and became asymptomatic postoperatively. Neither patient had a pancreatogram. One other patient with persistent upper abdominal pain and hyperamylasaemia, whose pancreas had been explored 18 months earlier for similar symptoms, had no demonstrable mass in the region of the pancreas by upper gastro-intestinal radiographic series or by palpation at laparotomy. A transduodenal pancreatogram, however, demonstrated a pseudocyst in the head of the pancreas. A cystoduodenostomy was performed with excellent clinical results.

Recurrent and/or new pseudocysts (*Table XII*)

Fourteen patients had recurrence of a pseudocyst and 2 had recurrence of pancreatic ascites without a pseudocyst. Two of the recurrent pseudocysts were treated elsewhere and are not included in *Table XII*. The second pseudocyst was located at a site different from the first in only 3 patients. In 5 of the remaining 9 patients, pancreatic ascites was associated with the first pseudocyst. It is purely speculative whether the recurrences were due to (*a*) inadequate therapy of the

Table IX: PREOPERATIVE HAEMORRHAGE

Clinical manifestation of bleeding	Source	Treatment	Results
Upper gastro-intestinal	Left gastric artery	Ligation+external drainage	Died
	Gastroduodenal artery	Ligation+external drainage	Died
	Gastroduodenal artery	Ligation+external drainage	Satisfactory
	Unknown	6 Units of blood	Satisfactory
	Unknown	4 Units of blood+external drainage	Ceased. Re-bled post-operatively. Died
Intracystic	Splenic artery	Ligation+distal pancreat-ectomy and splenectomy	Satisfactory
	Spleen	Ligation+distal pancreat-ectomy and splenectomy	Died

Table X: POSTOPERATIVE HAEMORRHAGE

Initial treatment	Clinical manifestation of bleeding	Source	Treatment	Results
External drainage	Intracystic	Unknown	Non-operative	Died
	External	Cyst wall	Pancreatoduodenectomy	Died
	External	Cyst wall	Packing	Died
	External	Cyst wall	Non-operative	Died
	External	Cyst wall	Non-operative	Survived
	External	Erosion of sump drain into splenic artery	Ligation of bleeder	Survived
Cystogastrostomy	Upper gastro-intestinal	Anterior gastrotomy wound	Ligation of bleeder	Survived

	Upper gastro-intestinal	Unknown	Non-operative	Survived
	Intracystic	Cyst wall	Non-operative	Died
Cystojejunostomy		Suture line leak and bleeding	Non-operative	Died

spontaneously and no specific source was identified at subsequent laparotomy.

Two patients became completely asymptomatic following rupture of the pseudocyst into the duodenum and colon respectively. The 3 patients who had rupture of a pseudocyst into the mediastinum and right pleural cavity improved temporarily after removal of the pleural fluid but subsequently needed surgical drainage of the pseudocyst. Most patients with rupture of a pseudocyst into the peritoneal cavity or with associated massive haemorrhage required vigorous intravenous replacement and urgent laparotomy.

At laparotomy in 2 patients the peritoneal cavity was lavaged but the collapsed pseudocyst was not drained; both patients survived but one developed a recurrent pseudocyst. In 10 patients the pseudocyst was drained externally; 4 died. Two patients had associated preoperative massive gastro-intestinal bleeding and died of sepsis, a third died of postoperative bleeding and sepsis and the fourth died of respiratory failure 3 days postoperatively. One of the patients with rupture of the pseudocyst into the right pleural cavity developed chronic pleural effusion and pancreatic ascites but became well following Roux-en-Y cystojejunostomy. Four patients had distal pancreatectomy and splenectomy without recurrence; one in whom the pseudocyst had ruptured into the spleen died of sepsis. Excluding the 6 patients with associated preoperative bleeding (3 of whom died), only 2 of 14 patients with acute rupture of a pseudocyst died—one of respiratory failure and the other of postoperative bleeding and sepsis.

b. Haemorrhage (*Tables IX, X*): Massive haemorrhage with a pseudocyst is an unpredictable serious complication. Four of 7 patients (57 per cent) with preoperative bleeding and 7 of 11 patients (64 per cent) with postoperative bleeding died. One patient bled both pre- and postoperatively. This complication is the prime cause of mortality in our patients with pseudocysts of the pancreas; 10 of 14 patients in the entire series who died bled either pr[illegible]or postoperatively. The remaining deaths were due to massive pulmonary embolism in 2, acute respiratory failure in the third and renal failure in the fourth.

c. Pancreatic ascites (*Table X*): Eighteen patients had 19 episodes of pancreatic ascites. The diagnosis of pancreatic ascites was based on chronic ascites with the triad of elevated serum amylase, elevated ascitic fluid amylase (346–97 000 Somogyi units/100 ml) and elevated ascitic fluid proteins (2·5–5·5 g/100 ml). A pseudocyst was palpable in only 2 patients, even after paracentesis, and radiographically demonstrable in only 10. In 2 cases a mass was not palpable even at laparotomy but intra-operative pancreatography revealed the pseudocyst (*Figs*. 5, 6). The patient whose pancreatogram is depicted in *Fig*. 6 is of special interest as he also had chronic pancreatic pleural effusion subsequent to rupture of the pseudocyst into the mediastinum and right pleural cavity. Following a Roux-en-Y cystojejunostomy of the abdominal portion of the pseudocyst, his pleural effusion disappeared in a few days. *Table V* details the types of treatment given and the results. Of the 4 patients who died, 1 had massive pulmonary embolism before operation, 2 patients had massive bleeding and rupture

Table IX: PREOPERATIVE HAEMORRHAGE

Clinical manifestation of bleeding	Source	Treatment	Results
Upper gastro-intestinal	Left gastric artery	Ligation + external drainage	Died
	Gastroduodenal artery	Ligation + external drainage	Died
	Gastroduodenal artery	Ligation + external drainage	Satisfactory
	Unknown	6 Units of blood	Satisfactory
	Unknown	4 Units of blood + external drainage	Ceased. Re-bled postoperatively. Died
Intracystic	Splenic artery	Ligation + distal pancreatectomy and splenectomy	Satisfactory
	Spleen	Ligation + distal pancreatectomy and splenectomy	Died

Table X: POSTOPERATIVE HAEMORRHAGE

Initial treatment	Clinical manifestation of bleeding	Source	Treatment	Results
External drainage	Intracystic	Unknown	Non-operative	Died
	External	Cyst wall	Pancreatoduodenectomy	Died
	External	Cyst wall	Packing	Died
	External	Cyst wall	Non-operative	Died
	External	Cyst wall	Non-operative	Survived
	External	Erosion of sump drain into splenic artery	Ligation of bleeder	Survived
Cystogastrostomy	Upper gastro-intestinal	Anterior gastrotomy wound	Ligation of bleeder	Survived

	Intracystic	Cyst wall	Non-operative	Died
Cystojejunostomy		Suture line leak and bleeding	Non-operative	Died

spontaneously and no specific source was identified at subsequent laparotomy.

Two patients became completely asymptomatic following rupture of the pseudocyst into the duodenum and colon respectively. The 3 patients who had rupture of a pseudocyst into the mediastinum and right pleural cavity improved temporarily after removal of the pleural fluid but subsequently needed surgical drainage of the pseudocyst. Most patients with rupture of a pseudocyst into the peritoneal cavity or with associated massive haemorrhage required vigorous intravenous replacement and urgent laparotomy.

At laparotomy in 2 patients the peritoneal cavity was lavaged but the collapsed pseudocyst was not drained; both patients survived but one developed a recurrent pseudocyst. In 10 patients the pseudocyst was drained externally; 4 died. Two patients had associated preoperative massive gastro-intestinal bleeding and died of sepsis, a third died of postoperative bleeding and sepsis and the fourth died of respiratory failure 3 days postoperatively. One of the patients with rupture of the pseudocyst into the right pleural cavity developed chronic pleural effusion and pancreatic ascites but became well following Roux-en-Y cystojejunostomy. Four patients had distal pancreatectomy and splenectomy without recurrence; one in whom the pseudocyst had ruptured into the spleen died of sepsis. Excluding the 6 patients with associated preoperative bleeding (3 of whom died), only 2 of 14 patients with acute rupture of a pseudocyst died—one of respiratory failure and the other of postoperative bleeding and sepsis.

b. Haemorrhage (*Tables IX, X*): Massive haemorrhage with a pseudocyst is an unpredictable serious complication. Four of 7 patients (57 per cent) with preoperative bleeding and 7 of 11 patients (64 per cent) with postoperative bleeding died. One patient bled both pre- and postoperatively. This complication is the prime cause of mortality in our patients with pseudocysts of the pancreas; 10 of 14 patients in the entire series who died bled either pre- or postoperatively. The remaining deaths were due to massive pulmonary embolism in 2, acute respiratory failure in the third and renal failure in the fourth.

c. Pancreatic ascites (*Table X*): Eighteen patients had 19 episodes of pancreatic ascites. The diagnosis of pancreatic ascites was based on chronic ascites with the triad of elevated serum amylase, elevated ascitic fluid amylase (346–97 000 Somogyi units/100 ml) and elevated ascitic fluid proteins (2·5–5·5 g/100 ml). A pseudocyst was palpable in only 2 patients, even after paracentesis, and radiographically demonstrable in only 10. In 2 cases a mass was not palpable even at laparotomy but intra-operative pancreatography revealed the pseudocyst (*Figs*. 5, 6). The patient whose pancreatogram is depicted in *Fig*. 6 is of special interest as he also had chronic pancreatic pleural effusion subsequent to rupture of the pseudocyst into the mediastinum and right pleural cavity. Following a Roux-en-Y cystojejunostomy of the abdominal portion of the pseudocyst, his pleural effusion disappeared in a few days. *Table V* details the types of treatment given and the results. Of the 4 patients who died, 1 had massive pulmonary embolism before operation, 2 patients had massive bleeding and rupture first pseudocyst, (*b*) failure to detect a second pseudocyst or source of leakage from the pancreatic ductal system at the first operation or (*c*) formation of a new pseudocyst.

Discussion

Pseudocysts of the pancreas are collections of fluid and debris, rich in pancreatic enzymes, in the region of the pancreas or within its parenchyma. In contrast to true cysts, pseudocysts do not have an epithelial lining and disruption of the pancreatic ductal system is a prerequisite. The subsequent course of this disruption, however, may vary widely from spontaneous healing to continuous leakage of pancreatic juice causing tense abdominal distension due to pancreatic ascites. Between these extremes, pseudocysts may form and these in turn may occasionally regress spontaneously by decompression into a pancreatic duct or into an adjacent organ. In a few cases in our series, cure followed radiologically demonstrated rupture into the common bile duct, duodenum or transverse colon. It is probable that such communications may also develop between the pseudocyst and other organs such as the stomach or small intestine. Eight per cent of our 131 pseudocysts regressed spontaneously; this is, in all likelihood, a minimal figure.

Despite the evidence of spontaneous regression, conservative non-surgical treatment is not advocated because of the frequency, unpredictability and severity of the potential complications associated with pseudocysts. Of our 131 pseudocysts, 42 (33·5 per cent) obstructed the duodenum or common bile duct, ruptured, leaked or bled. These hazards are more likely to occur during the immature phase of the development of the pseudocyst when the walls are tenuously formed by adjacent organs and peritoneal structures. This temporal relationship has considerable relevance in the debate concerning the advisability of urgent surgical operation to forestall the development of a cyst wall thick enough to permit safe internal anastomosis. Of the 20 pseudocysts which ruptured in our series, 17 did so within 4 weeks (*Table VIII*). In only 1 of these 20—a pseudocyst known to have been present for 4 weeks—was internal drainage thought to be feasible. These findings suggest that patients with suspected pancreatic pseudocysts should be kept under very close observation if the decision is made to delay surgery. We prefer to operate on mature pseudocysts and consequently keep these patients with fresh pseudocysts in hospital away from alcohol for 2–4 weeks during this phase of preoperative preparation. A number who continue to be symptomatic and are unable to eat adequately are helped by intravenous hyperalimentation.

Rupture into the peritoneal cavity and haemorrhage are the principal causes of death attributable to pseudocysts. Our experience of acute rupture into the peritoneal cavity has been more encouraging than is usually stated (Hanna, 1960), as only 1 of 7 patients died. In contrast, the results of haemorrhage have been dismal, 61 per cent of these patients dying (*Tables IX, X*). While an occasional patient may stop bleeding spontaneously, the chance of this occurring is unpredictable. Although 3 of 10 bleeding patients in whom no definitive procedure was done survived, it was apparent on critical review of the deaths that a number may well have been saved if early surgery had been instituted. From these experiences, a policy of rapid surgical intervention, even in apparently adverse circumstances, is now advocated for all patients with pseudocysts who have associated significant bleeding.

Pancreatic ascites is a much more common complication than reported in the past, occurring in 19 of our 131 pseudocysts (14·5 per cent), and must always be considered when an alcoholic patient develops fluid in the peritoneal cavity. The associated pseudocysts may be very difficult to demonstrate radiologically or clinically in these patients, even after paracentesis (*Table XI*), and may only be demonstrable at operation. We have also demonstrated the presence of a pseudocyst in such a patient preoperatively by pancreatography performed after cannulation of the pancreatic duct through a fibre-optic duodenoscope. Newer techniques, including sonagrams, may make future treatment more accurate. Recurrence of pseudocysts associated with pancreatic ascites has been inordinately high (40 per cent) in this series, but more recently, with specific delineation of the source of leakage and a knowledge of the ductal system gained through pancreatography performed at operation, successful definitive surgery has been the rule rather than the exception. Where the leak is associated with an immature pseudocyst or when no obvious pseudocyst is present, pancreatography is advisable. When distal pancreatectomy is performed, antegrade pancreatography is necessary to help in the determination of whether a more proximal ductal stenosis makes distal pancreaticojejunostomy (rather than simple ligation of the duct) essential. If the leak is identified in the wall of a mature pseudocyst, internal drainage is effective.

As more frequent pancreatography and more extensive exploration of the pancreas have been carried out, two important observations made by others have been confirmed. Anderson (1972) has pointed out that 23 per cent of the pseudocysts in his series were multiple. While the overall incidence of multiplicity was only 6 per cent in our series, the frequency of detection of more than one cyst has risen in recent years. Continuing symptoms following apparently adequate drainage of a well-defined pancreatic pseudocyst is sometimes due to failure to recognize a concomitant cyst at the first operation (*Table XII*). Secondly, severe symptoms of recurrent or persistent pancreatitis may be present when no pseudocyst can be delineated on a radiographic gastro-intestinal series or palpated in the pancreas, even at operation (Nardi et al., 1969). Retrograde pancreatography is essential in these circumstances as, apart from aspiration, this may be the only method of detecting the pseudocyst which may either fill with radio-opaque material or distort the pancreatic ductal system. The area of the head of the pancreas drained by the duct of Santorini has not been given the attention which it deserves (Anderson, 1972). Small cysts in this region may be strategically placed to produce obstruction of the common bile duct, bleeding from the gastroduodenal artery and severe continuing symptoms. In 2 cases where internal drainage was not performed, simple aspiration of 10 and 35 ml of fluid respectively rendered the patients asymptomatic.

Our most satisfactory results in pseudocysts of the head of the pancreas have been obtained by cystoduodenostomy where this has been feasible. In pseudocysts of the body and tail cystogastrostomy and cystojejunostomy produced comparable results. Cystogastrostomy, being quicker and easier, seems more desirable when the posterior wall of the stomach is adherent to the pseudocyst. Despite speculation that alkaline pancreatic secretions may bathe the antrum and stimulate the production of gastric acid to the point of causing gastroduodenal erosions or ulcerations, we have not encountered this sequence in practice. If at the time of operation the cyst wall is immature in that it does not lend itself to secure anastomosis, external drainage has been satisfactory. Drainage from the sinus tract may continue for several weeks, and it is essential that the drains are left in place until a well-defined tract has formed. No operation for a chronic pancreatic fistula has been required in this series. The main hazard encountered has been bleeding, possibly due to erosion by a sump tube of an adjacent vessel, and special care must consequently be taken in the selection and placement of drains. Finally, in recent years excision of the body and tail of the pancreas in selected cases (e.g. invasion of the spleen or kidney by the pseudocyst or in cases of bleeding or rupture) has been performed far more readily than in the past. The results of this more aggressive approach have been encouraging.

The occult osteomatous changes in the mandible in patients with familial polyposis coli

JOJI UTSUNOMIYA AND TADASHI NAKAMURA*

SUMMARY

Characteristic radio-opaque lesions were detected in the mandibular bone, most clearly on the panoramic X-ray, in 27 or 93·2 per cent out of 29 cases in 15 families with familial polyposis coli, including 21 cases without Gardner's stigmata, 7 cases with the incomplete syndrome and 1 with the complete syndrome.

Only 3 out of 19 members of these families who were free from polyposis had radio-opaque jaw lesions. The cases with polyposis of other types also showed a negative result.

The radiological diagnosis suggested that the lesions were of the character of endosteoma. Our observation is considered to be significant evidence in the understanding of the pathogenesis of Gardner's syndrome as well as a useful method for the early detection of carriers in the polyposis family.

THE term 'familial polyposis coli' (FPC) is defined in the present paper to include all the pathological conditions with numerous adenomatous polyps diffusely distributed in most parts of the large intestine regardless of familial occurrence and the association of extracolic lesions.

While studying FPC we have frequently observed minute extracolic neoplastic lesions, including Gardner's stigmata, osteoma (Gardner and Plenk, 1951) and/or soft tissue tumours such as epithelial cyst and fibrous tumours (Gardner and Richards, 1953), on detailed examination or at laparotomy. A thorough review of the world literature revealed a very high incidence of osteoma in the mandible (Chang et al., 1968; Utsunomiya et al., 1972) and the frequent appearance of abnormal dental growth (Fader et al., 1962) in cases which were reported as typical 'Gardner's syndrome' (synonymous with FPC with complete Gardner's syndrome as mentioned later in the present paper). We therefore decided to carry out radiological examination of the oral region on a routine basis in patients diagnosed as having FPC, and observed peculiar radio-opaque lesions detectable only by detailed dentomaxillar radiological examination techniques even in the cases without manifested associated changes.

Patients and methods

The cases submitted for the present study were divided into the following groups.

1. *Polypotic members of FPC families*

This group comprised a total of 29 cases (16 males and 13 females with an average age of 34·1 years) diagnosed as FPC and distributed in 15 independen families. A definite familial distribution has been detected in all but one family as shown in *Fig.* 1.

2. *Non-polypotic members of FPC families*

Nineteen members belonging to 9 of the above families were found to be free from polyposis at examination. They included 5 males and 14 females with an average age of 24·6 years (*Table I*, *Fig.* 1).

3. *Cases with intestinal polyposis of other types*

These included the following cases: 6 cases (3 males and 3 females with an average age of 20 years) of Peutz–Jeghers syndrome which were confirmed by the typical oral and digital pigmentation and scattered gastro-intestinal polyposis (Jeghers et al., 1949) with hamartomatous histological findings (Bartholomew et al., 1957); 1 male aged 33 years who was diagnosed as having juvenile polyposis coli by the characteristic histological findings as described by Veale et al. (1966); 4 males, with an average age of 58 years, who had several adenomatous polyps in the colon and rectum without familial occurrence.

Routine medical examination of all the cases was done, with particular emphasis being placed on radiology of the gastro-intestinal tract, fibrescopy of the stomach and colon, palpation and inspection of the body surface, systemic bone survey and anamnesis of tumour removal.

All these patients received routine dental and oral radiological examinations including craniography and intra-oral, mandibular body and panoramic radiography.

Medical findings

Colons removed from 23 patients revealed typical features, mostly of rather small, sessile adenomas diffusely distributed throughout the specimens, as seen in *Fig.* 2 which shows typical specimens from 3 members of family T78. Solitary or multiple malignant lesions were found in 10 patients. The remaining 5 non-operated patients showed characteristic radiological and endoscopic features of diffuse polyposis coli.

The associated neoplastic lesions were detected in diverse anatomical sites other than the gastro-intestinal tract, as listed in *Table I*. The patients were classified regarding the extracolic Gardner's stigmata, including osteoma and soft tissue tumours, into the following

examination was refused. The details of this family have been described by Ohtsuka (1973).

In none of these cases were lumps palpated around the jaw.

Dental findings

Characteristic radio-opaque lesions were detected in the maxillary and mandibular bone on panoramic X-rays in 27 out of 29 cases with FPC (93·2 per cent). In only 3 out of the 19 members of FPC families who were free of polyposis were such findings detected. The cases with polyposis of other types showed negative results.

The features of the lesions in question were most clearly demonstrated on panoramic X-rays (*Fig.* 3) compared with other radiological views.

The lesions have the following characteristics. They are localized and have increased radio-opacity with rather sharp borders; their size varies from 3 to 10 mm in diameter, and they are mostly round but sometimes with irregular margins; the degree of radio-opacity differs between lesions and within a lesion. The density is usually equivalent to that of bone cortex.

While they always appeared in the mandible, lesions in the maxilla were detected in 2 cases. In the mandible they were located mostly in the teeth-bearing part and never in the ramus. Many were found near the dental apex but never fused with it, while some were entirely separate from it.

The lesions were solitary in 7 cases and multiple, with up to 14 foci, in 19 cases. There was no observed significant relationship between the number of radio-opacities and the manifested associated lesions as shown in *Table I*. This is illustrated by the fact that the polypotic members of T78 family who were classified as simple FPC demonstrated most remarkable findings on panoramic X-rays (*Fig.* 3).

The lesions detected in the patients without polyposis were always solitary and very small.

The film of the case with complete Gardner's syndrome showed various lesions, including a small radio-opacity similar to those mentioned above, two composite odontomas, a large osteoma around the mandibular joint and many impacted teeth (*Fig.* 4). His daughter also showed a small radio-opacity in her mandible.

Another noticeable finding of the FPC patients was the frequent appearance of impacted teeth (in 11 cases or 35·7 per cent).

Discussion

Localized radio-opacities on X-rays of the mandibular and maxillary regions have been known as non-specific findings. The incidence of these in a normal population, however, may be rather low; focal radio-opacities of any type were detected on 26 (5·9 per cent) out of 438 panoramic X-ray films taken at the Department of Dental Radiology, Tokyo Medical and Dental University, in 1972; Boyne (1960) detected localized radio-opacities in only 1·4 per cent of full mouth X-rays of male patients at a dental clinic.

These data suggested that the incidence of radio-opacities of 93 per cent in cases with FPC was unusual. The fact that such radio-opacities were not detected in patients with other polyposis indicated that the condition is particularly associated with FPC.

Furthermore, our findings were considered to be different from simple condensing or sclerosing osteitis which accounts for most of the radio-opaque lesions seen on X-rays of the jaws on routine dental examination. The latter radio-opacities are usually solitary and occur around the dental apex in the premolar or molar region; contrary to this, our lesions were mostly multiple and also appeared in the incisor region. In addition the increased radio-opacity and the rather sharp margins indicate that they are more like osteomas than sclerotic lesions. Since no swelling around the jaw or in the oral cavity was detected clinically, lesions such as exostosis, torus or periosteal osteoma may be excluded. The lesions detected are therefore thought to correspond to central osteoma or endosteoma and the name 'occult osteomatous lesion' is proposed.

Biopsies of the lesions have not been carried out, first, because of the impossibility of obtaining sufficient material from such small lesions deeply hidden in the mandibular bone without extensive

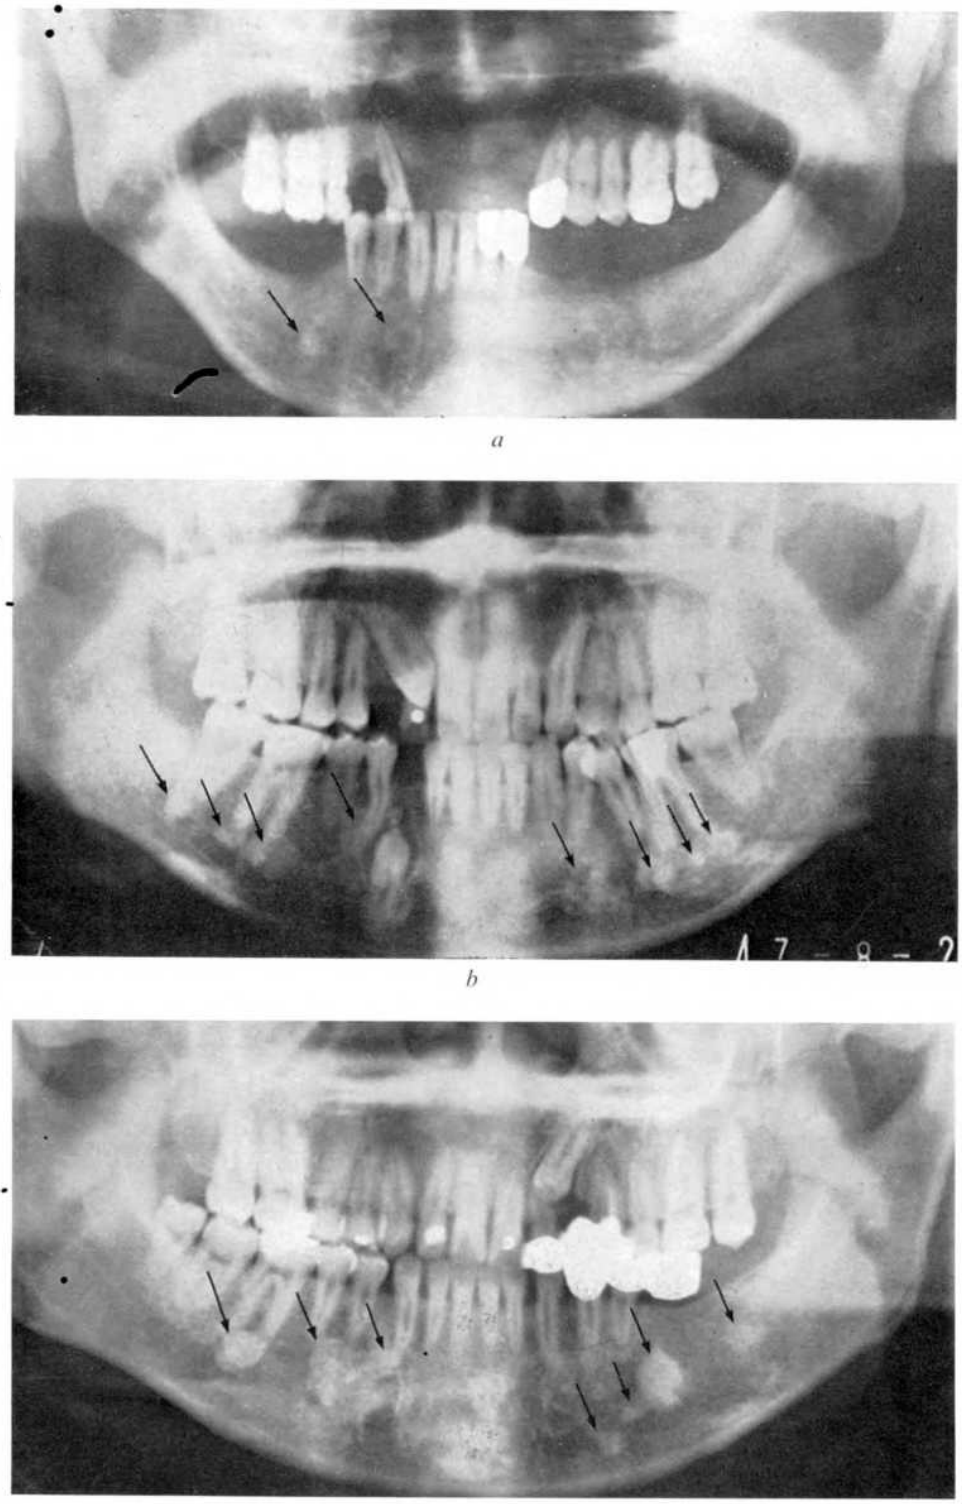

Fig. 3. Panoramic X-rays of the three polypotic members of family T78 shown in *Fig. 2*. *a*, Film of T78 II-f6 showing two round opacities with a rather sharp border located apart from the apex of the teeth in the right body of the mandible. *b*, Film of T78 -III-1 showing multiple (about eleven) opacities distributed in the body of the mandible, and an impacted canine. *c*, Film of T78 III-4 showing at least six radio-opaque foci. One of them located in the left premolar region is particularly large, 2 cm in diameter, and has quite a sharp border. The upper left canine is impacted.

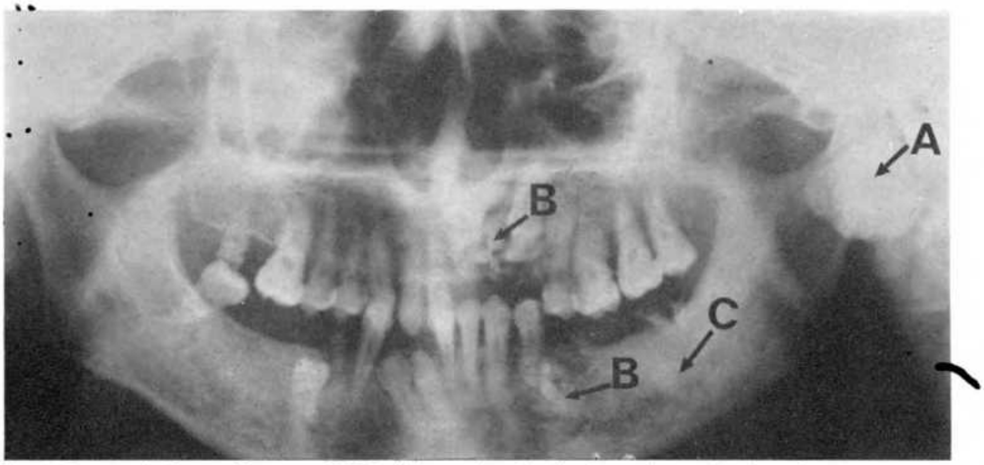

Fig. 4. Panoramic X-ray of a case of FPC with complete Gardner's syndrome showing a large osteoma (A), two composite odontomas (B), a focal radio-opaque lesion (C) and many impacted teeth.

damage to an unsymptomatic part of the patients, and secondly, because histological examination of a biopsy specimen, if it should be obtained, could not provide any more conclusive information than that provided by the radiological examination.

Although the explanation of the pathogenesis of the lesions will not be known until a large block of mandibular bone can be examined at necropsy of polypotic patients we believe that our findings are significant.

There is still dispute over the location of Gardner's syndrome in the classification of polyposis. McKusick (1962) considered that Gardner's syndrome belongs to a genetically isolated category from simple FPC, while Smith (1958, 1968) believed that the difference was merely a matter of expression of the associated traits of essentially the same disease with a single aetiology.

By comparing the essential characteristics, other than the associated stigmata, of the two diseases no significant differences were found by Utsunomiya et al. (1972).

In addition to this evidence, the present finding that in most of the cases with FPC, regardless of the association of Gardner's stigmata, osteomatous changes were detected in the mandible, which is the most common site of manifested osteoma in cases described as typical 'Gardner's syndrome', suggests that Gardner's syndrome and simple FPC should not be considered as different aetiological categories, and indicates that FPC has the potential to produce a variety of neoplastic lesions other than the colonic lesion. Utsunomiya et al. (1974) showed the very frequent association of adenomatosis of the stomach, and the occurrence of many other kinds of neoplastic lesion in this disease is known (Smith, 1958, 1968; McAdam and Goligher, 1970).

The frequent occurrence of osseous lesions, particularly in the mandible, in FPC in relation to the presence of impacted teeth in these patients might form the basis of another study.

In practice, the occult osteomatous changes described in this paper are considered to present a useful finding for the early detection of the polyposis carrier in the FPC family. In fact, we now perform routine panoramic X-rays of the jaws of members of a polypotic family and in many instances have predicted the presence of polyposis before rectal examination.

The continent ileostomy of Kock (ileal intra-abdominal reservoir)

Experience with 9 cases operated on for ulcerative colitis

JAN F. HALVORSEN AND PETER HEIMANN*

SUMMARY

A series of 9 patients with ulcerative colitis undergoing proctocolectomy and ileal intra-abdominal reservoir is reported. Eight patients are continent and 1 is incontinent. Early and late postoperative complications, work capacity and social and sexual functions are described.

PATIENTS with conventional ileostomies after proctocolectomy are generally held to adapt well to their situation (Biermann et al., 1966; Watts et al., 1966b; Goligher et al., 1968; Roy et al., 1970; Scott et al., 1970). After a long and disabling illness—in most cases ulcerative colitis—there is a marked improvement in the general physical condition of the patient, and the existence of an ileostomy may seem a reasonable price to pay for better health. The majority of patients return to their full pre-disease work capacity and their social activities are not mentionably restricted (Watts et al., 1966b; Goligher et al., 1968; Roy et al., 1970; Scott et al., 1970). If questioned closely, however, a significant number of patients with an ileostomy admit that they have problems. There are many drawbacks of even a well-functioning ileostomy: the flow of intestinal contents is more or less continuous in a quantity of about 600 ml/24 hours (Goligher et al., 1968), is not voluntarily controlled and necessitates the continual wearing of external bags. Even with modern appliances there is always the possibility of leakage and unpleasant odour (DiZerega et al., 1967). Skin irritation and maceration from the effluent or the bag glue are the most frequent complications and occur in 24–70 per cent of patients (Biermann et al., 1966; Watts et al., 1966b; DiZerega et al., 1967; Roy et al., 1970). The wearing of bulky external appliances also puts some restraint on the social lives of the patients, especially during the bathing season and during periods of fashionable body exposure. Some patients find that care of the ileostomy and the appliances requires too much time (Roy et al., 1970). Sexual dysfunction occurs in 25–30 per cent of cases (Watts et al., 1966b; Roy et al., 1970), and probably is due to the combined effect of the rectal excision and the presence of an artificial anus. A small number of patients simply cannot adjust to a life with an ileostomy and feel miserable and crippled (Watts et al., 1966b; Roy et al., 1970).

These problems prompted Kock (1969, 1971, 1973) to create an ileal intra-abdominal reservoir that gave patients the possibility of having voluntary control of emptying, and made the wearing of bags unnecessary. In a recent publication (Kock, 1973) he reported the results in a series of 90 patients. Other authors (Akovbiantz and Kock, 1972; Beahrs and Adson, 1973; Cameron, 1973; Halter, 1973; Schaudig et al., 1973; Beahrs et al., 1974) have published smaller series. The present paper reports the results in 9 patients with ulcerative colitis treated with proctocolectomy and ileal intra-abdominal reservoir.

Materials and methods

Nine patients (6 men and 3 women) with ulcerative colitis, 7 with total and 2 with near total involvement of the colon, underwent proctocolectomy with the creation of an ileal intra-abdominal reservoir. These patients were followed up during the period from December 1971 to April 1974 (observation time 2–28 months). The age distribution of the patients was 16–56 years, and the duration of the colitis ranged from 9 months to 15 years. Six patients were operated on electively and 3 during an acute attack. In 8 patients the operation was done as a one-stage procedure and in 1 patient as a two-stage procedure.

The construction of the reservoir was performed as shown in *Fig.* 1. The terminal 15 cm of the distal ileum were left untouched, and the 30 cm of ileum proximal to this were folded and sutured together along the antimesenteric border with a continuous 3/0 Dexon suture. The legs of the U were then opened, the incision being made 3 cm longer in the proximal leg in order to separate the outlet from the inlet. The mucosa was sutured with a continuous 3/0 Dexon suture. The terminal ileum was then partly intussuscepted into the reservoir, making a 4-cm long nipple, this being fixed with eight to ten 2/0 silk sutures through the intestinal wall with the ileostomy tube in place. The intestinal plate formed by the opened ileum was then folded and closed in two layers with 3/0 Dexon. The reservoir was manipulated into shape by putting it in between the mesenteric leaves. The patency of the reservoir and the valve was tested by injecting air into it through a catheter while clamping the afferent limb. Removal of the catheter should not result in leakage of air through the outlet. The air was removed by reinserting the catheter. The ileostomy opening in the skin was made at a site lower down than is usual for a conventional ileostomy, so as to be

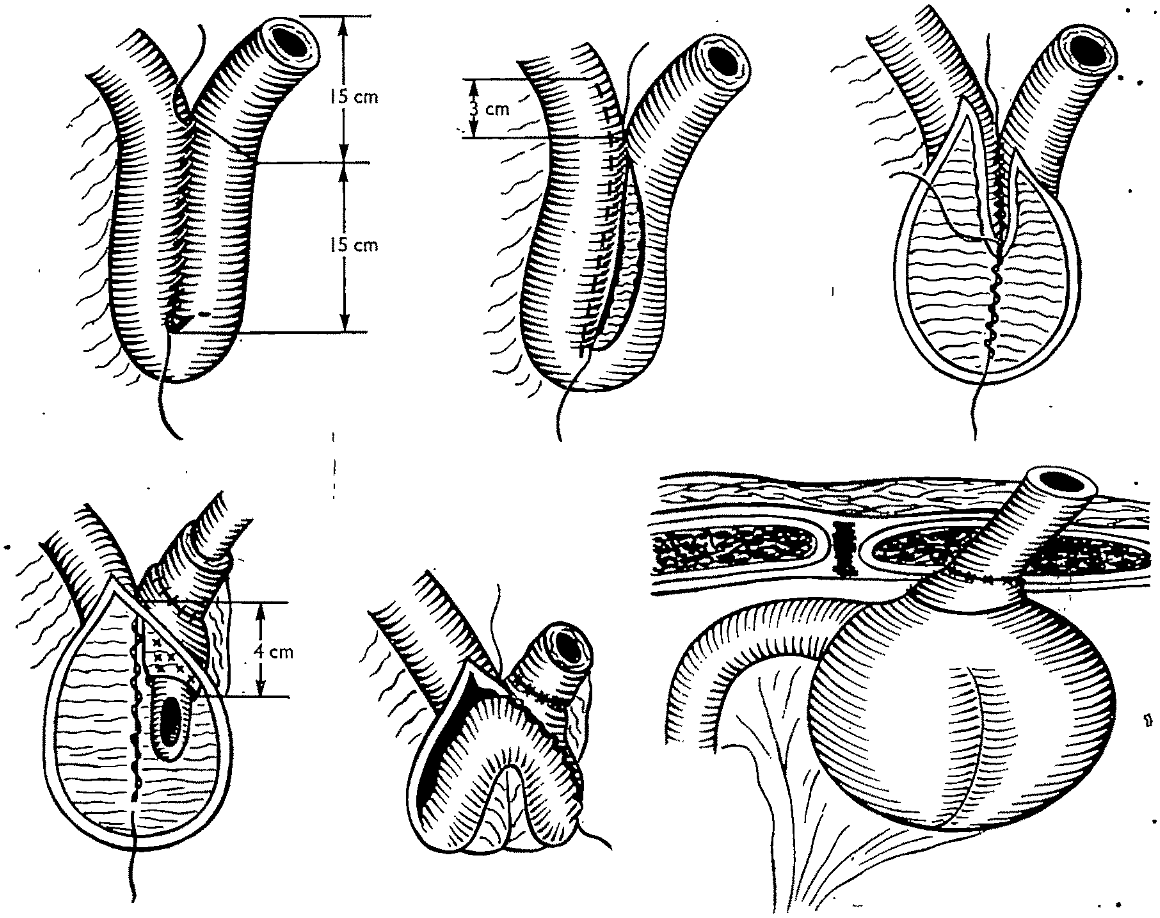

Fig. 1. Diagrammatic representation of the operative procedure.

situated well below the waistline. From this skin opening a tunnel was made slightly obliquely through the rectus muscle, and the terminal segment of the ileum pulled through the channel. The reservoir was fixed to the anterior abdominal wall with interrupted silk sutures and the space lateral to the reservoir closed by suturing the edge of the mesentery to the parietal peritoneum. Excess ileum was resected and a flat ileostomy made by suturing the skin to the cut edge of the intestine with interrupted 2/0 chromic catgut sutures. The ileostomy tube was left in place to drain the reservoir for the first 7 postoperative days through a wide bore tube into a plastic bag. On the eighth day the ileostomy tube was removed and then reintroduced at 3-hourly intervals. It was still left *in situ* at night for another 3–4 days, after which time emptying of the reservoir was performed at increasing intervals until after 3–4 months' time only 3–5 emptyings a day were necessary. The stoma was covered by a small bandage between emptyings.

Five reservoirs were originally made according to Kock's procedure B without a nipple and 4 according to procedure C with a nipple (Kock, 1973). Three patients who originally had no nipple have been reoperated on with the construction of a nipple because of incontinence after the first operation. At present therefore 7 reservoirs have a nipple. *Table I* lists age and sex, duration of the disease, duration of and discontinuance of steroid treatment in relation to the operation and degree of involvement of disease.

Results

There was no mortality. All the patients are alive and have been followed up. *Table II* lists the early and late postoperative complications.

Early complications

In 2 cases there was troublesome bleeding from the pelvic cavity during the operation. One was managed by tamponade from below and removal of the pack the next day, and the other underwent reoperation on the third day to ensure haemostasis. One patient had a reoperation on the seventh postoperative day for intestinal obstruction caused by adhesions. Three patients developed a fistula from the reservoir to the abdominal wound, but they all healed spontaneously

Table I: DETAILS OF THE PRESENT SERIES

Case no.	Sex	Age (yr)	Duration of disease	Duration of steroid therapy	Discontinuance of steroid therapy	Degree of involvement
1	M	35	9 mth	4 mth	3 mth	Total
2	M	37	15 yr	4 yr	2·5 mth	Near total
3	M	16	12 yr	3 mth	1 yr	Total
4	M	56	2 yr	2 mth	After operation	Total
5	M	31	5 yr	9 mth	After operation	Near total
6	F	29	13 yr	1 mth	6 yr	Total
7	F	47	4 yr	2 mth	4 mth	Total
8	M	25	3 yr	1 yr	After operation	Total
9	F	34	6 yr	2 mth	2 mth	Total

Table II: POSTOPERATIVE COMPLICATIONS

Postoperative complications	No. of cases
Early	
Haemorrhage from the pelvic cavity	2
Intestinal obstruction (adhesions)	1
Fistula from reservoir to abdominal wound	3
Transient hepatic insufficiency (cirrhosis)	1
Late	
Partial disinvagination of the nipple	3
Perineal sinus (silk sutures)	1
Pulmonary embolus	1

in the course of 1–2 weeks with the ileostomy tube left in place. Two of these patients were operated on during an acute attack of ulcerative colitis and 1 following 2 months of continuous steroid therapy. One patient, who prior to the operation had cirrhosis of the liver, developed transient hepatic insufficiency with a moderate jaundice that disappeared after 2 weeks.

Late complications

The main late complication has been difficulties in introducing the tube into the reservoir. This occurred in 3 patients in whom a nipple had been constructed. X-ray studies with the injection of contrast through the stoma demonstrated lengthening of the efferent limb due to partial disinvagination of the nipple. Since the nipples were to some extent still intact, the simplest operation of shortening the efferent limb was performed. All of them are now continent, though occasionally the patients wear a bag for safety. One patient developed a perineal sinus that persisted for 1 year from which silk sutures repeatedly were removed and which has now healed. One patient suffered a pulmonary embolus 2 months after the operation and was successfully treated with Streptokinase and Marevan.

Continence

Table III lists the results as regards continence. Four patients are continent for gas and fluid, empty their reservoirs about five times daily and never wear bags. Four patients are continent, but occasionally wear a bag for safety in certain situations. One patient is incontinent and always wears a bag.

Sexual function

One male patient is impotent and 1 female has dyspareunia.

Table III: CONTINENCE AFTER OPERATION

Result	With nipple	Without nipple
Continent	6	2
Incontinent	1	0

Social function

The incontinent patient feels somewhat restricted socially.

Work capacity

Eight patients have returned to full pre-disease work capacity. One recently operated patient has not yet returned to work.

Discussion

The incidence of postoperative complications in this small series is about the same as that of other published series of ulcerative colitis treated with proctocolectomy and conventional ileostomy (Watts et al., 1966a, b; Roy et al., 1970; Scott et al., 1970). Three patients developed a transient fistula from the reservoir to the abdominal wound. Two of them were operated on during an acute attack and 1 following 2 months of continuous steroid therapy. It is generally accepted that these factors predispose to delayed healing and anastomotic leakage (Watts et al., 1966a; Scott et al., 1970; Kock, 1973). In 3 cases partial disinvagination of the nipple occurred, causing lengthening of the efferent limb and difficulties in introducing the tube. They were all treated by shortening the efferent limb, and though they are still continent and experience no difficulties in inserting the tube, the correct operation would probably have been re-laparotomy and reconstruction of the nipple. We did not scarify the serosal surface when making the nipple in these 3 patients, as has since been recommended by Kock (1973). It seems that the presence of the ileal intra-abdominal reservoir did not seriously jeopardize the postoperative course in our series.

In 1 case a persistent perineal sinus developed from which silk sutures were removed repeatedly by curettage. The sinus healed after 1 year. This patient was operated on during an acute attack of ulcerative colitis after 9 months of continuous steroid treatment. Although it is believed that the sinus was caused by a foreign body reaction to silk, these factors may have contributed to its development and persistence. Watts et al. (1966b) found that the incidence of perineal sinus increased fourfold if steroids were administered for more than 6 months prior to surgery.

Eight patients have returned to their work and have regained full pre-colitis work capacity. One patient who has recently been operated on is still incapacitated.

The patient with the perineal sinus also developed migrating arthritic symptoms in the joints of the upper extremities. These symptoms first appeared after the operation, but there were no objective signs of joint disease. Watts et al. (1966b) reported persistent arthritic symptoms in 5 out of 131 patients treated surgically for ulcerative colitis. They concluded, however, that the symptoms were not due to true colitic arthritis.

A 56-year-old man has become impotent and a 47-year-old woman has developed dyspareunia after the operation. This is a not uncommon experience after rectal excision (Watts et al., 1966b). The incidence of postoperative sexual dysfunction increases with advancing age (Watts et al., 1966b; Roy et al., 1970), and may well be a reflection of the physical and psychological effects of a major operation with the creation of an artificial anus in individuals whose sexual function is already waning. The other patients have not reported any change in their sexual habits, though 2 young unmarried males express a certain anxiety as to the reaction of the opposite sex when their affliction is discovered.

Originally 5 reservoirs were made without a nipple. Three of these have later been fitted with a nipple because of incontinence. At present 7 reservoirs have a nipple. Eight patients are continent for gas and fluid and empty their reservoirs three to five times daily, but 4 of them occasionally wear a bag for safety, though most of the time they cover the stoma with a bandage. One patient who originally had a nipple is incontinent, probably owing to disinvagination of the nipple. This, however, has not been verified because he does not wish further examination and treatment. Thus 6 out of the 7 reservoirs with a nipple and both the remaining reservoirs without a nipple are continent. It seems that the nipple practically ensures continence.

The patient who was operated on in two stages originally had a conventional ileostomy that was converted to an ileal intra-abdominal reservoir because of skin maceration. He is now continent, and his skin is normal.

The 8 continent patients are very satisfied with their stomas, and lead normal or near normal lives both professionally and socially. The incontinent patient feels restricted socially and is also impotent.

We have not performed absorption studies in our patients, but none of them has hitherto shown any clinical signs of deficiencies. Jagenburg et al. (1971) studied the absorption of D-xylose, fat and L-phenylalanine in 10 patients with a conventional ileostomy and in 10 patients with an ileal intra-abdominal reservoir, and found no differences in the two groups. The bacterial flora of the reservoir is intermediate between the flora of the effluent from a conventional ileostomy and that of normal faeces (Branberg et al., 1972). Morphologically there is flattening of the villi with an intact brush border, a finding that may indicate an adaption to the change in the microbial population (Kock, 1973). There is, however, no change in the disaccharidase activity (Kock et al., 1972).

According to our experience with 9 patients the continent ileostomy of Kock is a valuable alternative to the conventional ileostomy. It is also recommended in patients who for some reason are unhappy with their conventional ileostomy, especially those with skin problems. The reservoir should be made as an elective procedure, and in acute situations a conventional ileostomy is preferred. This may easily be changed into an ileal intra-abdominal reservoir at a later date. A reservoir should not be made in cases of Crohn's disease of the colon, because a recurrence in the reservoir will necessitate the removal of too much ileum (Kock, 1973). In our experience the following technical details seem important. The efferent limb should be short and brought out slightly obliquely through the rectus muscle. When constructing the nipple the serosal surface should be coagulated with diathermy and the fixing sutures of the nipple should be silk to prevent disinvagination of the nipple. Difficulties in introducing the tube may indicate that disinvagination has occurred. If verified by stomography and endoscopy the correct treatment of this complication is re-laparotomy and reconstruction of the nipple.

Torsion of the testis: a review of 22 cases

Improved diagnosis and earlier correction

M. G. GREANEY*

SUMMARY

Greater awareness of the possibility of torsion of the testis and earlier exploration has led to the saving of 14 out of 19 acutely twisted testicles.

PREVIOUS reports have shown that up to 62 per cent of patients presenting with torsion of the testis have required orchidectomy. Delays in diagnosis and exploration are said to account for this high figure (Barker and Raper, 1964; Allan and Brown, 1966). This paper reviews all the cases of torsion admitted to two surgical units at the Royal Infirmary, Sheffield, during the years 1963–73, when there was greater awareness of this condition.

Materials and methods

Twenty-two cases with the final index diagnosis of torsion of the testis were reviewed. All presented as acute surgical emergencies, except for 3 patients. These 3 cases presented as outpatients with recurrent testicular pain. In 2 the pain was in the right testis of 4 months' and 5 years' duration respectively, the latter patient having previously had an undescended left testis removed at herniotomy. In the third there was recurrent left testicular pain.

All the cases were explored, and the diagnosis of torsion confirmed at operation.

In every case the affected testis was in the scrotum, and torsion was of the intravaginal type. The anatomical anomalies, which are bilateral in torsion of the testis, have previously been described (Clarke, 1956; Angell, 1963; Barker and Raper, 1964). Clinically, the abnormalities are seen in the standing patient as bilateral horizontally lying testes.

Incidence

This series does not include children under 13 as they are not admitted to this hospital. Although the maximum incidence is described as being in the late teens it should be noted that 54 per cent of this series were older, indeed one patient was 63 years old, and it would appear that torsion of the testis can occur at any age (*Table I*).

Clinical features

Classic descriptions of acute torsion of the testis remark on the sudden onset of pain in the groin, sometimes associated with vomiting, and the finding of a swollen and acutely tender affected testis, with oedema and erythema of the overlying scrotum. The clinical features of the 19 patients presenting acutely are shown in *Table II*. This shows that the most important clinical signs are: (1) a tender swollen testis; (2) the horizontal lie of either the affected or the opposite testis; (3) the absence of urinary symptoms. Only one patient had dysuria but since he had a positive urine culture he may have had a concomitant urinary infection.

It should be noted that: (*a*) pyrexia is non-specific; (*b*) although the onset of pain is rapid in contrast to epididymitis it is not normally sufficiently sudden to be noted as such; (*c*) the condition is found equally on either side.

Table I: AGE DISTRIBUTION

Age (yr)	No. of cases
13–20	11
21–30	8
31+	3

Table II: CLINICAL FEATURES IN 19 CASES PRESENTING ACUTELY

Clinical feature	No. of cases	%
Pain		
Sudden onset	1	5
Scrotal	17	90
Confined to abdomen initially	2	11
Subsequent radiation to groin/lower abdomen	6	32
Nausea and vomiting	3	16
Tender, swollen testis	19	100
Horizontal lie of affected testis	7	37
Horizontal lie of contralateral testis	8	42
Dysuria	1	5
Temperature noted in admission notes in 8 cases		
Normal	3	
36·4–37·8 °C	5	
Urine samples in 6 patients		
No cells on microscopy	4	
Many WBC/high power field	1	
Single WBC/high power field	1	
Organisms cultured but no WBC	1	
Side affected in total number of patients (22)		
Right	10	
Left	12	

Recurrent torsion

Of the 22 patients (including the 3 presenting non-acutely), 15 gave a history of similar episodes of previous testicular pain. All were of short duration, no more than 3 hours, and had occurred, on occasions, over a maximum period of 2 years. Seven of the 15 complained of a single episode of pain, the earliest being 5 years previously and at that time this patient had fixation of the affected testis.

---

* Royal United Hospital, Bath.

Table III: DURATION OF SYMPTOMS PRIOR TO ADMISSION AND SUBSEQUENT TREATMENT

Duration of symptoms (hr)	Orchidopexy	Orchidectomy
0–6	11	
7–12	1	1
13–48	—	—
48+	2	2
Duration unknown	2	
Non-acute	3	

Treatment

As previously mentioned, all the cases were surgically explored using scrotal incisions, the diagnosis confirmed and the necessary operative treatment instituted. Treatment was fixation (orchidopexy) of the affected testis if considered viable after untwisting the spermatic cord. The testicle was fixed to the spermatic cord with interrupted thread sutures to maintain an upright position. The tunica vaginalis was then usually everted and the scrotum closed with catgut to the dartos and clips to skin. If the testis appeared gangrenous and remained so after allowing time for improvement of the circulation orchidectomy was performed. In one case viability was doubtful and orchidopexy was later complicated by a scrotal abscess.

The unaffected testis requires fixation at the time of operation to prevent subsequent torsion and this was performed in 19 of the 22 cases.

Barker and Raper (1964) emphasized the importance of early operation and subsequent outcome and *Table III* shows the necessary management in relation to the duration of symptoms before admission to hospital.

In 3 of the cases the postoperative course was complicated by local inflammation. In 2 there was scrotal abscess formation, one of these patients being found to have many white cells in the urine in a sample taken preoperatively. In the other patient a stitch abscess developed.

Follow-up

At the time of discharge from the outpatients' clinic 17 of the 19 salvaged testicles were reported as normal. Both of the abnormal testes were in patients who had suffered from postoperative scrotal infection in whom the affected testis was then atrophic. Seven of the 19 responded to a recent request to come for re-examination. Only one had evidence of serious damage to the affected testis and he had been one of the patients in whom a scrotal abscess had complicated the postoperative course.

Discussion

Torsion of the testis unless quickly diagnosed and treated leads to loss of the testis. In this series of 22 cases in only 4 was the testis definitely lost and in another the testis probably atrophied. In 3 orchidectomy was performed and in the other 2 there was postoperative scrotal abscess formation. This compares favourably with results in earlier papers: Angell (1963), 4 orchidectomies in 14 patients; Barker and Raper (1964), 18 in 38 patients; Allan and Brown (1966), 36 in 58 patients; Chapman and Walton (1972), 32 in 67 patients.

The results of our series would seem to show a greater awareness of the condition at the present time and of the necessity for early diagnosis and operation. In all cases in which there is doubt over the diagnosis of an acutely tender, swollen testis, especially one noticed to be in a horizontal position with the patient standing and with the contralateral testis in a similar position, exploration should be carried out.

Acknowledgements

I am grateful to Mr D. H. Randall and Mr C. Jones for allowing me to review these patients who have been under their care.

Surgical sterilization by vasectomy and its effect on the structure and function of the testis in man

A. S. GUPTA, L. K. KOTHARI, A. DHRUVA AND R. BAPNA*

SUMMARY

The early and late effects of vasectomy have been investigated in 40 men. Besides histopathological examination, the volume of the testis and its total content of testosterone-secreting Leydig cells have been measured.

The volume of the testis showed a wide normal variation (5·3–23·3 ml) but was not significantly changed by vasectomy. One month after vasectomy widespread degeneration of the germinal epithelium, thickening of the basement membrane and some inter-tubular fibrosis were observed. Spermatogenesis had ceased. However, cases examined 2–3½ years later showed an essentially normal structure with active spermatogenesis. This indicates that regeneration does occur spontaneously, even without recanalization. Whether the sperms formed are functionally normal remains uncertain.

The normal total Leydig cell volume was 2·2 ± 0·4 ml/testis in young adults and showed a modest increase after vasectomy, rising to 2·5 ± 0·5 ml after 1 month and 2·6 ± 0·5 ml after 2–3½ years. The findings have been discussed in the light of Steinach's (1927) original hypothesis that vasectomy can rejuvenate ageing males by improving the endocrine function of the testis.

BILATERAL vasectomy is gaining wide popularity as a contraceptive measure, particularly in developing countries such as India where it forms a major part of the population control programme. The changes that occur in the testis as a result of occlusion of its outflow tract have been repeatedly investigated in laboratory animals but the results have been variable, ranging from a marked degeneration of the seminiferous tubules and proliferation of the testosterone-secreting Leydig cells (Steinach, 1927; Houssay, 1955; Kothari et al., 1973) to practically no change at all (Harrison and Macmillan, 1954; Baillie, 1960; Smith, 1962). Besides species variation, some of the factors possibly involved are the site of seminal occlusion, interference with testicular blood supply and the accuracy of histopathological interpretation.

In view of this uncertain situation we have investigated the post-vasectomy testicular changes directly in man, paying particular attention to Steinach's (1927) original hypothesis that vas occlusion leads to a hyperplasia of the Leydig cells—the main basis for his claim that it rejuvenated ageing males.

Materials and methods

This study is based on 40 healthy fertile males between 30 and 60 years of age; these were divided into three groups:

Group A: Twenty young adults (30–35 years) undergoing vasectomy for sterilization.

Group B: Ten elderly males (50–60 years) vasectomized prior to prostatectomy (uncomplicated cases).

Group C: Ten vasectomized subjects undergoing recanalization (30–35 years).

Techniques

1. *Vasectomy*: After 1 per cent xylocaine infiltration the scrotum was incised in the midline. The vas on both sides was isolated by dissection and divided between two clamps, almost midway between the epididymis and external inguinal ring. About 1 cm of vas was totally removed and the cut ends tied firmly with silk. After attaining perfect haemostasis, the wound was closed with interrupted sutures and sealed.

2. *Open testicular biopsy*. The scrotal skin was infiltrated with 1 per cent xylocaine under proper asepsis, and a small incision was made anteriorly, midway between the upper and lower poles of the testis. The tunica vaginalis was opened. A nick in the tunica albuginea brought the testicular tissue bulging out and a piece was carefully removed by a neat cut. With gentle manipulation and a little pressure on the testis, a second biopsy piece was taken through the same cut in the albuginea. After achieving haemostasis, the wound was closed in layers and sealed. Analgesics and an anti-inflammatory drug (Tanderil, Geigy) were given if the patient complained of any pain.

The biopsy pieces were immediately fixed in Bouin's fluid. Paraffin blocks were prepared in the usual manner, using alcohol for dehydration and toluene for clearing. Sections were cut at 5 μ thickness and stained with haematoxylin and eosin.

3. *Testicular volume*: The three dimensions of the testis were first measured at their widest part along the scrotal skin using Vernier callipers. The thickness of the intervening tissues (skin surface to tunica albuginea) was then carefully measured at the site of the biopsy incision with a second pair of sterilized callipers and subtracted from the external measurements to give the true testicular dimensions. In some cases the whole testis was delivered from its tunicae and directly measured, but the previous procedure was found sufficiently accurate to make this unnecessary.

The volume of the testis was calculated by the formula, $V = \frac{4}{3}\pi r_1 r_2 r_3$, presuming the testis to be an ellipsoid such that r_1, r_2 and r_3 are its radii in the three planes (Ahmad et al., 1969).

---

* Ravindranath Tagore Medical College, Udaipur, India.

4. *Total Leydig cell volume*: This was quantitatively estimated by the histometric point-counting method. The details of the technique and its experimental verification have already been described (Kothari et al., 1972). A Leitz-type integrating eyepiece was used and, since the volume of each testis had already been determined *in situ* without any fixation or shrinkage, the total Leydig cell content could be precisely calculated in absolute terms, i.e. ml/testis.

In all cases only the left testis was investigated as being a representative of both.

Results

Testicular volume

The volume of the testis showed a large normal variation, ranging from 5·3 to 23·3 ml in the 30 males prior to vasectomy (groups A and B). The mean volume was somewhat lower in the older group of 50 years and over, compared with that in the young subjects, the values being 11·9 ± 6·5 ml and 13·6 ± 5·1 ml respectively. The difference, however, is not statistically significant.

Table I shows the testicular volume before and 1 month after vasectomy. In the older patients the volume did show a slight decrease in most instances but the change was not significant. It appears, therefore, that vasectomy does not produce any consistent change in the size of the testis which normally shows a wide variation.

Histopathology

Advancing age has been found to give rise to significant changes in the human testis (Kothari and Gupta, 1974). Thus, males above 50 years of age show scattered areas of tubular atrophy, increase in connective tissue and an appreciable proliferation of the Leydig cells. These signs of normal senility have to be kept in view while evaluating the post-vasectomy changes in testicular structure, and for the same reason they have been studied separately in the young and the old.

One month after vasectomy the testicular biopsies showed significant changes in all the 20 young adults. Marked degeneration of the germinal epithelium was evident in most of the tubules and spermatogenesis appeared to be arrested at the level of spermatocytes. A few tubules, however, still appeared normal. It was interesting to observe that the spermatogonia or basal cells withstood the degeneration and were well preserved in all the tubules.

The tunica propria which forms the limiting membrane of the seminiferous tubules showed appreciable thickening. It was now composed of several layers of wavy connective tissue lamellae and was distinctly wider than normal. A generalized increase in the intertubular connective tissue was also evident in most cases. There was, however, no evidence of increased vascularity, inflammatory reaction or necrosis.

Histologically, the interstitial or Leydig cells appeared almost unaffected by vasectomy. In some cases the collapse of the seminiferous tubules and increase in intertubular connective tissue made them more prominent, but there was no cytological evidence of active proliferation.

In males above 50 years of age the post-vasectomy changes were essentially similar but were more marked and widespread. Spermatogenesis was arrested at the spermatocyte stage in most of the tubules. The thickening of the tubular basement membrane and intertubular fibrosis, which normally accompany ageing, had been further accentuated by vasectomy. The Leydig cells stood out prominently in large clusters, and if compared with the picture in a normal (non-vasectomized) young adult would convey an impression of marked proliferation. However, we have already observed an increase in the Leydig cells as a part of the normal ageing process (Kothari and Gupta, 1974) and no further increase on account of vasectomy could be established unequivocally by histopathological examination.

Ten cases coming for recanalization 2–3½ years after vasectomy have also been included in this study since they provide an opportunity to study long term effects in young healthy adults. The need for recanalization arose because of the death or chronic illness of an only male child.

The testicular volume in these cases ranged between 8·3 and 15·1 ml with a mean of 12·2 ± 4·9 ml. This is somewhat lower than the testicular volume 1 month after vasectomy in young males (13·4 ± 4·7 ml), but the difference is not statistically significant.

Testicular biopsy revealed signs of full differentiation of germ cells and active spermatogenesis in all 10 cases. There was also clear evidence of moderate Leydig cell hyperplasia. In 4 cases, however, a vacuolating degeneration confined to a few scattered tubules was present along with some thickening of the tunica propria and intertubular fibrosis. No correlation could be established between the time lapse after vasectomy and the presence of these changes. The significant fact which emerged was the presence of active spermatogenesis in all the cases, 2–3½ years after vasectomy, along with some Leydig cell hyperplasia; scattered degeneration of a few tubules was superimposed in 40 per cent of cases. Some of these histopathological changes are shown in *Figs.* 1–5.

Total Leydig cell volume

The total Leydig cell volume has been found to be 2·2 ± 0·4 ml/testis in young healthy adults. In relative terms the Leydig cells constitute approximately 15 per cent of the testicular volume. The effect of vasectomy is shown in *Table II*.

The absolute Leydig cell content has shown a quantitative increase in all the young subjects as a result of vasectomy, but the change is modest and fails to reach a statistically significant level 1 month after vasectomy ($P > 0{\cdot}05$). However, in the recanalization cases the increase is more pronounced and statistically significant ($P < 0{\cdot}05$) compared with the normal Leydig cell content of young adults, both the groups being exactly matched for age (30–35 years). The

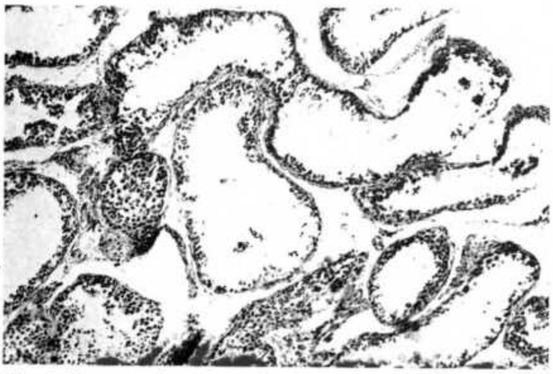

Fig. 3. Degeneration of germinal epithelium and arrested spermatogenesis in a young adult 1 month after vasectomy. Most of the tubules appear distended. HE. (×80.)

mean value has risen from 2·2 ± 0·4 ml/testis to 2·6 ± 0·5 ml/testis, an increase of about 18 per cent.

In the 10 subjects above the age of 50 years the total Leydig cell volume, which was already as high as 2·9 ± 0·7 ml/testis due to ageing, showed only a minor and inconsistent fluctuation after vasectomy. Although the number of cases is small, it appears that vasectomy does not significantly influence the Leydig cell content of the testis in older subjects, in contrast to the increase observed in the young.

Table I: EFFECT OF VASECTOMY ON TESTICULAR VOLUME

Group	No. of cases	Testicular volume (ml) Before vasectomy	Testicular volume (ml) After vasectomy	P
Young (30–35 yr)	20	13·6 ± 5·1	13·4 ± 4·7	>0·10
Elderly (50–60 yr)	10	11·9 ± 6·5	10·0 ± 5·2	>0·05

Table II: EFFECT OF VASECTOMY ON TOTAL LEYDIG CELL VOLUME IN YOUNG ADULTS (30–35 YEARS)

Group	No. of cases	Absolute Leydig cell volume (ml/testis) Mean	Absolute Leydig cell volume (ml/testis) Range
Vasectomy cases	20		
Before vasectomy		2·2 ± 0·4	1·2–3·1
One month after vasectomy		2·5 ± 0·5	1·7–3·3
Recanalization cases 2–3½ years after vasectomy	10	2·6 ± 0·5	1·7–3·5

Discussion

In many parts of the world today vasectomy would rank amongst the most commonly performed elective surgical procedures. It may easily be presumed that it leads to no other consequence except sterility because there are hardly any postoperative complications or complaints. However, many apparently unrelated long term effects can often go unnoticed, and the question whether vasectomy merely interrupts the testicular outflow or produces, in addition, any subtle structural, endocrinal, immunological or other changes is well worth asking, particularly when vasectomy is being performed in such large numbers.

In the present study on human subjects widespread degeneration of the seminiferous tubules has been found in all the cases 1 month after vasectomy. Spermatogenesis naturally ceases. This conforms to our earlier observations in the dog where marked degenerative changes (Kothari et al., 1973) and histochemical alterations in the distribution of lipids, cholesterol, glycogen and enzymes have been found (Kothari and Mishra, 1973). The basal germ cells, however, escape this degeneration, either because they are furthest from the lumen or because they are the most primitive and undifferentiated. In any case, their preservation upholds the possibility of regeneration of the seminiferous tissue later on. Vasectomy also produces some thickening of the tunica propria of the seminiferous tubules. How this affects the functional qualities of the tunica—regulation of fluid exchange and maintaining adequate pressure for onward movement of tubular contents—is uncertain. A similar thickening of the tunica propria, however, occurs in several unrelated conditions of the testis associated with degeneration of the germinal tissue, e.g. Klinefelter's syndrome, exposure to X-rays or ionizing radiations etc. (Velardo, 1958).

That this post-vasectomy degeneration is followed by a spontaneous regeneration is now in no doubt. The testicular structure has been found to be essentially within normal limits, with active spermatogenesis, in subjects examined 2–3½ years after vasectomy. Recanalization is, therefore, not necessary to initiate the regenerative process, and the testis, after a lapse of time, seems to accommodate to its obstructed outflow. Whether the sperms formed in the vas-occluded testis (or the testis with congenital absence/obstruction of the vas) are functionally normal also seems doubtful, since Kubota (1969) has found, by electron microscopy, degenerative changes in the spermatids and sperms of vasectomized men. However, after the vas has been recanalized, successful pregnancies frequently do occur.

It would be reasonable to presume that this post-vasectomy degeneration results from an increase in the intraluminal pressure as the fluid accumulates behind the obstruction. Disparity amongst different species could possibly be related to the absorptive capacity of the epididymis which buffers any change in pressure. The absence of any inflammatory reaction, haemorrhage, etc., in all the cases clearly shows that the testicular changes are not due to any faulty operative technique or to an inadvertent interference with the blood supply.

Endocrine testis

It is obvious that in elderly persons or vasectomized individuals in whom spermatogenesis has lost its importance, the endocrine function of the testis still has a vital role to play and continues to do so even in advanced old age. We have therefore made a quantitative estimate of the total Leydig cell content before and after vasectomy in absolute terms (ml/testis), which makes the result independent of any change in testicular size. The accuracy of the method employed has already been experimentally demonstrated (Kothari et al., 1972).

In young healthy adults the total Leydig cell volume has been found to be 2·2 ± 0·4 ml/testis, with a range of 1·2–3·1 ml (*Table II*). Vasectomy has produced a modest but consistent increase in the total Leydig cell volume which has reached a mean value of 2·5 ± 0·5 ml/testis after 1 month. In subjects examined 2–3½ years after the operation the mean Leydig cell volume has increased significantly to 2·6 ± 0·5 ml/testis. Males above 50 years of age have shown a high Leydig cell content (2·9 ± 0·7 ml/testis) even without vasectomy. This seems to be a part of the ageing process and possibly reflects a pituitary-sponsored hyperplasia initiated by a negative feedback from a declining testosterone secretion (Kothari and Gupta, 1974). Vasectomy does not significantly alter this picture. It appears, therefore, that the elderly vasectomized male can have a larger than normal Leydig cell volume, but this seems to be the result of ageing rather than vasectomy—a fact which could have misled many earlier observers. It may well reflect a hypotestosteronism rather than hypertestosteronism, much like an iodine-deficiency enlargement of the thyroid. On the other hand, the consistent increase in Leydig cell volume in young adults is a direct result of vasectomy. A similar increase has been quantitatively demonstrated in dogs (Kothari and Mishra, 1972; Kothari et al., 1973). This is significant, although it must be admitted that an increase in the size of an endocrine gland does not necessarily imply an increase in hormone output.

The cause of post-vasectomy Leydig cell hyperplasia is uncertain. It may possibly involve some yet undefined humoral feedback from the degenerating seminiferous tubules to the anterior pituitary which could stimulate, through its gonadotropins, the endocrine Leydig cells or promote their differentiation from existing precursor cells (Johnsen, 1972). A continuous lysis of the sperms could keep the process going even when the germinal epithelium has recovered from its immediate post-vasectomy degeneration.

The final question still remains: Has vasectomy any real rejuvenating effect? The increase in Leydig cells observed by us, the rise in androgen-dependent constituents of the semen (fructose and acid phosphatase; Kothari, 1974) and the enhanced libido experienced by some vasectomized males do seem to uphold the possibility, but the fact that these changes are more evident in the young rather than the aged is discouraging. A long-term follow-up of vasectomized individuals and repeated testosterone estimations may help to resolve this interesting controversy.

The relationship between ultrasound assessment and angiography in occlusive arterial disease of the lower limb

J. CHAMBERLAIN, E. HOUSLEY AND A. I. S. MACPHERSON*

SUMMARY

The Doppler ultrasound technique has been used to assess the haemodynamics of the peripheral circulation in patients with arterial disease. Using this method the resting pressure index and the response after exercise of the systolic pressure at the ankle was determined in 62 limbs.

Following exercise, four patterns of abnormal response to exercise were found and graded in severity from 1 to 4. A single aorto-iliac lesion was associated with a normal or slightly reduced resting pressure index but with a severe reduction of pressure (grade 3–4) after exercise. A single femoropopliteal lesion was usually associated with a low resting pressure index but only a slight (grade 1–2) fall after exercise.

A low resting pressure index and a severe post-exercise grade were found in patients with multiple occlusions. Disease of the profunda femoris artery was associated usually with both a low resting pressure index and a grade 3–4 post-exercise curve.

THE importance of functional measurements in the assessment of patients with peripheral vascular disease has been recognized in recent years. To be widely applicable, such a test must be not only accurate and reproducible but also easily and rapidly performed. Strandness et al. (1966), Yao et al. (1969) and Yao (1970) have reported favourably on methods based on the Doppler effect using a beam of ultrasound. With this technique it is possible to measure accurately the systolic blood pressure in small peripheral vessels, even when it is much reduced, and to observe the response of these pressures to exercise.

It seemed desirable to try to find out how far such a simple non-invasive technique could supplement or even replace the most established investigation in peripheral arterial disease, namely arteriography. The object of the present study was to use the ultrasound technique to make a functional assessment of patients with occlusive vascular disease affecting the lower limbs and to relate the findings to the appearances on angiography.

Patients

There were 31 patients in the study of whom 25 were male and 6 female. The ages ranged from 43 to 75 years. All the patients complained of intermittent claudication, often associated with absent ankle pulses and, in many cases, with other signs of ischaemia due to atherosclerotic occlusive vascular disease.

Methods

The systolic blood pressure was measured at the posterior tibial artery in the supine position using a Parks 810 Doppler Flowmeter and a pencil-shaped probe, from which is transmitted a beam of ultrasound of 10 MHz/second. The probe was used as a pulse detector and the systolic blood pressure measured with a sphygmomanometer cuff placed just above the ankle. The principles and use of this technique have been described by Strandness et al. (1966). The measurement was first made at rest and then every minute for 15 minutes after exercise. This was a simple two-step exercise, the patient stepping up to a stool and down at a fixed rate of 60 steps/minute for 5 minutes, or until he was forced to stop

because of claudication. The ratio of the ankle systolic pressure to the brachial systolic pressure was calculated (pressure index). In normal subjects the value of the pressure index is almost always greater than 1·0 (Yao et al., 1969; Yao, 1970). In patients with occlusive vascular disease there is usually, though not always, a resting ankle systolic pressure index of less than 1·0.

After exercise in the normal subject there is an increase in leg blood flow and a fall in peripheral resistance because of dilatation of muscle vessels. The increased flow is greater than the fall in peripheral resistance, and the systolic pressure in the limbs tends to rise immediately after exercise. In occlusive vascular disease, although there is a rise in systemic blood pressure and cardiac output, the resistance of the lesion limits the increase in flow to the leg. The vasodilatation of muscle blood vessels diverts a large proportion of the limited flow and thus there is a fall in pressure in the distal arteries.

We have found four grades of severity of abnormal ankle pressure response after exercise (*Fig.* 1). In the type 1 curve there is no change in pressure after exercise although the resting pressure index may be normal or below normal. The type 2 curve shows a moderate fall in pressure after exercise with a fairly quick rise to the pre-exercise value. In the type 3 curve there is a moderate to severe fall in the resting value, and this

has returned to the pre-exercise value by the end of the 15-minute post-exercise monitoring period, and in type 4 there is a profound fall in ankle systolic pressure and the pressure has not returned to the pre-exercise value by the end of 15 minutes.

Angiograms were carried out by routine radiological methods by either the percutaneous femoral or translumbar route. The angiograms were then assessed by a method based on that described by Morton et al. (1967). Each segment was given a score varying from 0 to 4 (*Table I*), depending upon the type and extent of disease demonstrated. The assessment of this according to the pathology present is shown in *Table II*.

Results

Resting pressure index (*Fig*. 2)

A single aorto-iliac stenosis was usually associated with a normal or only slightly reduced index. The resting pressure index tended to be lower when there were extensive or multiple arterial occlusions, and particularly when the profunda femoris vessels were involved. In patients with iliac stenosis and femoropopliteal occlusions there was a significant difference ($P<0{\cdot}05$) in those with and without disease of the profunda femoris, but the considerable overlap makes the measurement of little value in the individual case. The resting pressure index and the angiographic scores are compared in *Fig*. 3 and a correlation is demonstrated which is highly significant ($P<0{\cdot}001$). Where radiographic involvement of the profunda vessels could be demonstrated there was also both a low resting pressure ratio and a low angiographic score.

Post-exercise pressure curves

The types of post-exercise curves are plotted against the angiographic score in *Fig*. 4. It is evident that a low angiographic score, indicating multiple occlusions, and disease of the profunda femoris vessels are both associated with a type 3 or type 4 post-exercise curve. The correlation between the type of curve obtained and the angiographic score is significant ($P<0{\cdot}001$). However, there is a group of 10 cases in which a type 3 or 4 curve is found with an angiographic score of 8–10. Eight of these cases were single aortic or aorto-iliac occlusions with normal femoropopliteal segments and all the aorto-iliac occlusions had a type 3 or 4 curve.

A clear correlation also exists between the resting pressure index and the type of post-exercise curve (*Fig*. 5).

Discussion

The technique described is atraumatic, easy to perform repeatable and requires no expensive recording apparatus. The general validity of the measurements appears to be confirmed by the significant correlation between the post-exercise pressure curves and the degree and extent of the occlusive process as measured by numerical scoring of the angiogram. The severity of the functional impairment in single aorto-iliac lesions is clearly demonstrated. The disparity between the functional measurement and angiographic score in such patients suggests that the scoring system underestimates the 'severity' of such lesions.

This study confirms the limit of the pressure index in patients with proximal lesions only. These patients may have a relatively high pressure index and the significance of the lesion only becomes evident on exercise.

In the few patients with proved narrowing of the profunda femoris artery (the main collateral vessel to the lower limb) the post-exercise pressures were always significantly lowered. However, the wide overlap between the various groups makes it impossible to use the technique as a method for defining the anatomical distribution of disease in an individual patient. This fact, together with the need for accurate knowledge of the anatomy of the lesions when planning surgery, means that the present technique cannot replace angiography but is a valuable supplementary investigation.

The technique provides an objective record of the functional importance of an occlusion in the main artery whether demonstrated clinically or radiologically. It is also of use in excluding or assessing the significance of peripheral vascular disease in doubtful or atypical cases of intermittent claudication without recourse to angiography, and finally it provides an easy and reliable test with which to assess progress of the disease or the effect of therapy.

Phenol sympathectomy in the treatment of intermittent claudication: a controlled clinical trial

T. FYFE AND R. O. QUIN*

SUMMARY

Twenty-five patients with intermittent claudication were randomly allocated to treatment either by injection of phenol into the lumbar sympathetic chain or by injection of local anaesthetic subcutaneously. On the day after the injection, sympathectomy, assessed by skin temperature change, was achieved in 85 per cent of the phenol group.

At 1 month subjective improvement was claimed by 45 per cent of the patients in the sympathectomized group and by 64 per cent in the control group; at 3 months the figures were 25 and 45 per cent respectively.

Treadmill testing at two exercise loads showed no significant difference in claudication distance or stopping time between the two groups. Calf blood pressure response following exercise was not affected by sympathectomy.

There is no subjective or objective evidence that phenol sympathectomy improves intermittent claudication.

LUMBAR sympathectomy either by operation or by injection of phenol or alcohol is claimed to benefit patients with intermittent claudication (Smithwick, 1957; MacKenzie and Loewenthal, 1962; Reid et al., 1970), but this has been disputed (Richards, 1971). There is little objective evidence to support either claim, however, and there have been no controlled clinical trials reported.

Materials and methods

Twenty-five patients (24 males and 1 female) were included in the trial. All had a history of intermittent claudication which predominantly affected one leg and which had been stable for at least 3 months. They had palpable femoral pulses with diminished or absent pulses distally and all showed a drop in the calf blood pressure of the affected leg after exercise. The patients were randomly allocated to a 'phenol group' or to a 'control group'. Those in the phenol group were given an injection of 5 ml of 1 : 15 solution of phenol into the lumbar sympathetic chain at each of two levels by the method of Reid et al. (1970). The control group received lignocaine subcutaneously into the lumbar region on the affected side.

The assessment was made by a physician who did not know to which group the patients belonged. On two occasions, separated by at least a week, before injection and again at 1 month and 3 months after injection the patients were asked if there had been any change in the distance they could walk; they were exercised on a treadmill, and the blood pressure changes in the legs after exercise were measured.

Treadmill testing consisted of exercising at 2 m.p.h. at a 15° gradient followed by 2 minutes' rest, then exercising at 3 m.p.h. at 20°. The patient indicated the onset of claudication and stopped the treadmill when he felt compelled to do so. Three such tests were carried out at each visit with an interval of at least 30 minutes' rest between each test. Thus six estimates of time to the onset of claudication and stopping time were obtained for each patient before injection for comparison with six measurements after injection.

Systolic blood pressure changes in both legs were measured following exercise at 3 m.p.h. at 20° once at each visit. The blood pressure was measured using sphygmomanometer cuffs placed around the calves just below the tibial tuberosities and an ultrasonic Doppler instrument to detect the onset of flow in the posterior tibial or dorsalis pedis arteries. Measurements were made every 2 minutes for a period of 10 minutes and again at 15 minutes after exercise. The blood pressure in the affected leg was expressed as a ratio of that in the other leg. The blood pressure in the right arm was also measured at rest and the leg : arm blood pressure ratio calculated. All blood pressures were recorded with the patient semi-recumbent in a reclining chair. The leg pressure in the leg : arm blood pressure ratio is thus subject to an increased hydrostatic effect, which will increase the ratio in these patients relative to the ratio as derived in other reports, where the patient is horizontal.

The effectiveness of the sympathectomy in the phenol group was assessed by the surgeon who allocated the patients to the treatment group and who carried out the injections. This was done by comparing the mean temperature at ten sites on the dorsum of each foot after exposure of the limbs to room temperature for half an hour. The temperatures were measured with a thermocouple before injection, on the day after and at 3 months after injection.

Student's *t*-test was used to analyse the significance of results.

Results

Thirteen patients were randomly allocated to the phenol group and 12 to the control group. Eleven patients in the phenol group had a successful

sympathectomy judged clinically and by a temperature difference of at least +2 °C between the limbs (*Table I*) on the day after injection. The other 2 patients in the phenol group did not show any change in temperature in the treated limb and the results in these patients will be considered separately. For analysis the phenol group was composed of the 11 patients who had a successful sympathectomy on the day after injection. It can be seen (*Table I*) that the cutaneous vasodilatation declined and at 3 months only 4 of these patients had a sympathectomy detectable clinically. However, the treated limb was relatively warmer in all cases at 3 months ($P < 0{\cdot}05$ in 8 out of 11 cases). In the control group 1 patient defaulted after receiving the placebo injection, leaving 11 patients in the control group for analysis. There was no significant temperature change following placebo injection.

Table II compares the phenol group with the control group. The groups are well matched in terms of disease severity judged by treadmill testing and by the leg : arm blood pressure ratio. The mean age of the patients in the control group is slightly less than that of the phenol group but this difference is not significant.

In the phenol group 45 per cent (5 patients) claimed to be improved 1 month after injection and at 3 months 25 per cent (2 out of 8; 3 patients refused to return for further treadmill testing). This compares with 64 and 45 per cent at 1 month and 3 months in the control group. If the patient who defaulted from the control group is regarded as a failure the percentage claiming improvement would fall to 58 per cent at 1 month and 42 per cent at 3 months.

Both the patients who had an unsuccessful sympathectomy following phenol injection said they were

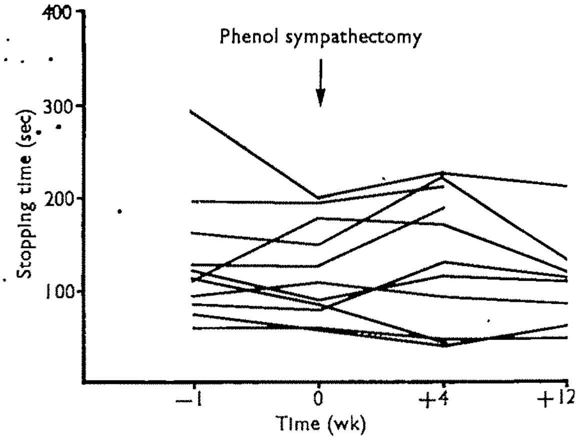

Fig. 1. Mean stopping times for individual patients in the phenol group at each series of assessments after exercise at 2 m.p.h. and 15°.

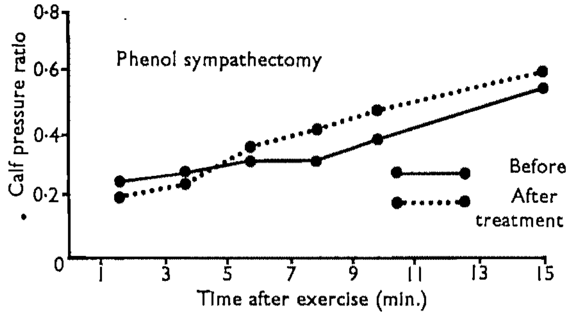

Fig. 2. Mean calf blood pressure ratio for the phenol group following exercise at 3 m.p.h. and 20°.

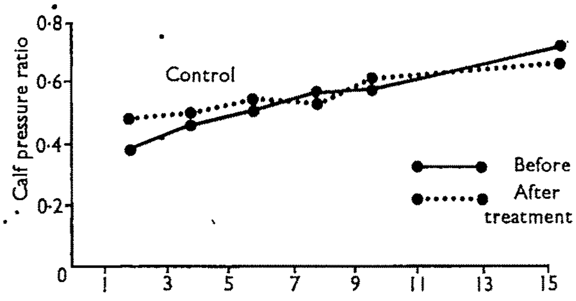

Fig. 3. Mean calf blood pressure ratio for the control group following exercise at 3 m.p.h. and 20°.

improved, but even if these patients were included the percentage claiming improvement would still not be better than that in the control group, being 54 per cent at 1 month and 40 per cent at 3 months. Of the 4 patients with a clinical sympathectomy still apparent at 3 months, 2 claimed improvement in walking distance.

The results for treadmill assessment are shown in *Tables III* and *IV*. Only the mean results before and after treatment are shown because it was found that analysing the results for each series of assessments did not alter the overall picture. This is illustrated in *Fig*. 1 which shows the mean stopping time for each patient in the phenol group at 2 m.p.h. and a 15° gradient at each visit. The phenol group were not significantly better than the control group in any treadmill assessment. None of the 4 patients who still had a clinical sympathectomy at 3 months showed improvement on treadmill testing.

The calf blood pressure response to exercising at 3 m.p.h. at 20° is shown for the phenol group in *Fig*. 2 and for the control group in *Fig*. 3. Standard deviations were large and are not shown. Injection did not alter the response in either group and there was no significant difference between the groups.

Discussion

A clinically obvious sympathectomy with a temperature increase of at least 2 °C relative to the other limb was achieved on the day following injection in 85 per cent of the patients injected with phenol. At 3 months after injection, only 4 patients had a clinically obvious sympathectomy, but there was evidence of some residual effect in the remainder since all showed an increase in temperature relative to the other limb. It is known that the blood flow response following surgical sympathectomy is greatest initially and declines thereafter (Lynn and Barcroft, 1950). The results in the patients with a sustained clinically obvious sympathectomy, were, however, no different from the others.

We have shown that sympathectomy does not improve intermittent claudication in this selected group of patients with femoropopliteal disease. Indeed it should be noted that the subjective results in our control group are as good as those claimed by others for sympathectomy in patients with a similar level of peripheral arterial disease (Mavor, 1955; MacKenzie and Loewenthal, 1962; King et al., 1964; Myers and Irvine, 1966; Reid et al., 1970). It is well known that such patients exhibit a marked placebo response (Hamilton and Wilson, 1952) and account should be taken of this when assessing results of sympathectomy.

We conclude that phenol sympathectomy produces no objective benefit in intermittent claudication.

A clinical trial designed to discover if the primary treatment of varicose veins should be by Fegan's method or by an operation

F. S. A. DORAN AND MARY WHITE*

SUMMARY

1. *The current practice of operating upon patients with varicose veins as the treatment of choice costs more than £15 millions a year.*

2. *The bulk of this expense is due to the length of time that patients are kept in the ward. If they were treated as outpatients, either by Fegan's method or by operation, the cost would be reduced to one-tenth of what is now spent. Even if the operation were done on a 'short-stay' basis the cost would be reduced to one-third or less.*

3. *Although the long term results of Fegan's method are uncertain there is no doubt that it gives better immediate results than an operation. Moreover, there is no particular type of varicosity or shape of limb which precludes its use.*

FROM 1855 to 1905 varicose veins were treated by sclerosing injections. Ligation at the saphenofemoral junction and stripping dates from 1905. It did not become the standard treatment in this country until about 1950. Now it is the most frequently performed operation in general surgery. Each year in England and Wales 150 000 patients are operated on for varicose veins (Lees, 1969) at a cost of more than £15 millions.

The problem is to decide whether these patients can be treated more cheaply by using Fegan's compression-injection method of sclerotherapy and diverting the money saved to some other surgical task.

If Fegan's method is to become the primary treatment of choice it must be proved that it is as good a treatment as the operation of saphenofemoral ligation and stripping of the long saphenous trunk.

It has been asserted that a patient with varicose veins can be treated by Fegan's method at the cost of £9·77 per head as compared with £44·22 per head if he were operated upon (Piachaud and Weddell, 1972). At its face value this represents an annual saving in England and Wales of over £5 millions.

Under prevailing surgical management it would save nearly three times that amount because the calculation made by Piachaud and Weddell (1972) rested on the fact that the patients who were operated on were sent home in 3·7 days. By contrast, as the authors point out, the latest 'mean national length of stay for varicose vein cases' ranges from 7·5 to 15·7 days, with an average of 11·7 days. This average length of stay in the ward coincides closely with the official figure of 10·5 days (Lees, 1969). At the present time in the Birmingham region 10 days as an inpatient costs £110 (Wall, 1973), and an actuarial analysis by the same regional board found that the average cost per operation was £13·30, inclusive of the pay of the doctors, the nurses, the domestics and 'others', and covering the cost of drugs, dressings and equipment. As a round figure, therefore, the cost of operating on a patient with varicose veins, taking England and Wales as a whole, is about £125.

Piachaud and Weddell (1972) calculated that the cost of the operation alone was £12, which coincides closely with the figure given above of £13·30. This leaves little doubt that the financial disadvantage of the operative method is almost entirely due to the time spent in the ward. The great financial advantage of Fegan's method, which is an outpatient treatment, rests upon this fact.

However, operation can also be performed on outpatients, as has been found both in North America (McPheeters, 1945) and in Britain (Stevens and Dudley, 1961). This practice would virtually abolish the financial disadvantage of treating varicose veins by operating on them.

Before this issue can be decided, properly constructed clinical trials must be carried out or the patients may suffer. Finance must not be the overriding factor. According to Piachaud and Weddell (1972) and to Seddon (1973) the two methods being compared in this trial are of equal merit.

Design of the trial

The present trial was arranged as a random series. Fegan's method was used on all the patients born in a year with an even number, while those born in a year with an odd number were operated upon.

Patients who were operated on were not managed as outpatients because to do so would tend to limit the operation to stripping of one saphenous vein. Clinically, this would have biased the trial in favour of Fegan's method because some patients need more than one long saphenous vein stripped. Therefore the patients were kept in hospital for 2 days because there is no limit to the amount of surgery possible on this basis (Doran et al., 1972).

To avoid confusion the comparison between the two methods was based on whether additional treatment was prescribed at the end of the first year and again at the end of the second year after treatment. Either additional treatment was given or it was not. Two years was chosen as the length of the trial. It is well known that with benign conditions of low morbidity it is difficult to maintain an efficient follow-up for longer.

---

* Mid-Worcestershire Hospitals of Bromsgrove and Kidderminster.

Method of injection-compression

The method used in this trial followed that of Fegan closely, except that ethamolin was used throughout. The quantity injected at each site was 0·5–1 ml. Not more than three or four sites were injected at the same visit into one limb (Fegan, 1964). The 'empty vein' technique recommended by Fegan (1960) was used routinely. There were no overdose effects.

The compression was obtained by bandaging a Sorbo rubber pad over the site of the injection and the application of a full length two-way-stretch elastic stocking over the bandages, held up where needed by a suspender belt, and worn day and night (Fegan, 1965).

Furthermore, the patients were instructed to walk 3 miles a day and to avoid standing (Fegan, 1965). The bandaging was examined at the hospital each week. At these visits the previous injection sites were examined and any additional injections required were given. Compression over the injection sites was maintained for 6 weeks at least after the last injection.

Before taking the final decision that the treatment was complete the patients were told to remove the stockings and bandages 2 days before they were due to be seen and to take a bath, replacing the stockings only. In this way the skin, corrugated by the bandages, has time to become smooth, which makes the final assessment much easier. If no additional injections were needed the elastic stockings alone were reapplied for a further 6 weeks, when the stockings were discarded and the patient followed up at increasing intervals up to 2 years from the start of the treatment.

Patients

Because the division and ligation of the incompetent perforating veins in the leg which cause ulceration are so uniformly successful in healing the ulcer it was considered unjustifiable to include such cases in the trial. Therefore, all patients presenting with an open varicose ulcer were excluded. This series numbers 331 patients with varicose veins uncomplicated by ulceration. Of this total, 182 patients were treated primarily by Fegan's method and 149 were operated upon. In the Fegan group 98 patients had bilateral varicose veins and in 84 the varicosities were confined to one leg. In the group who underwent operation 73 had bilateral varicose veins and in 76 they were unilateral. Presented as individual limbs, the Fegan group contains 280, and the operative group 222, making a total of 502 limbs for the whole series.

Results

As far as possible the observations made in this trial will be reported as the number of limbs treated. In patients with bilateral varicose veins the severity and the site of the varicosities in the two limbs seldom match. Furthermore, after a patient with bilateral varicosities has been treated one limb may be a success and the other a failure.

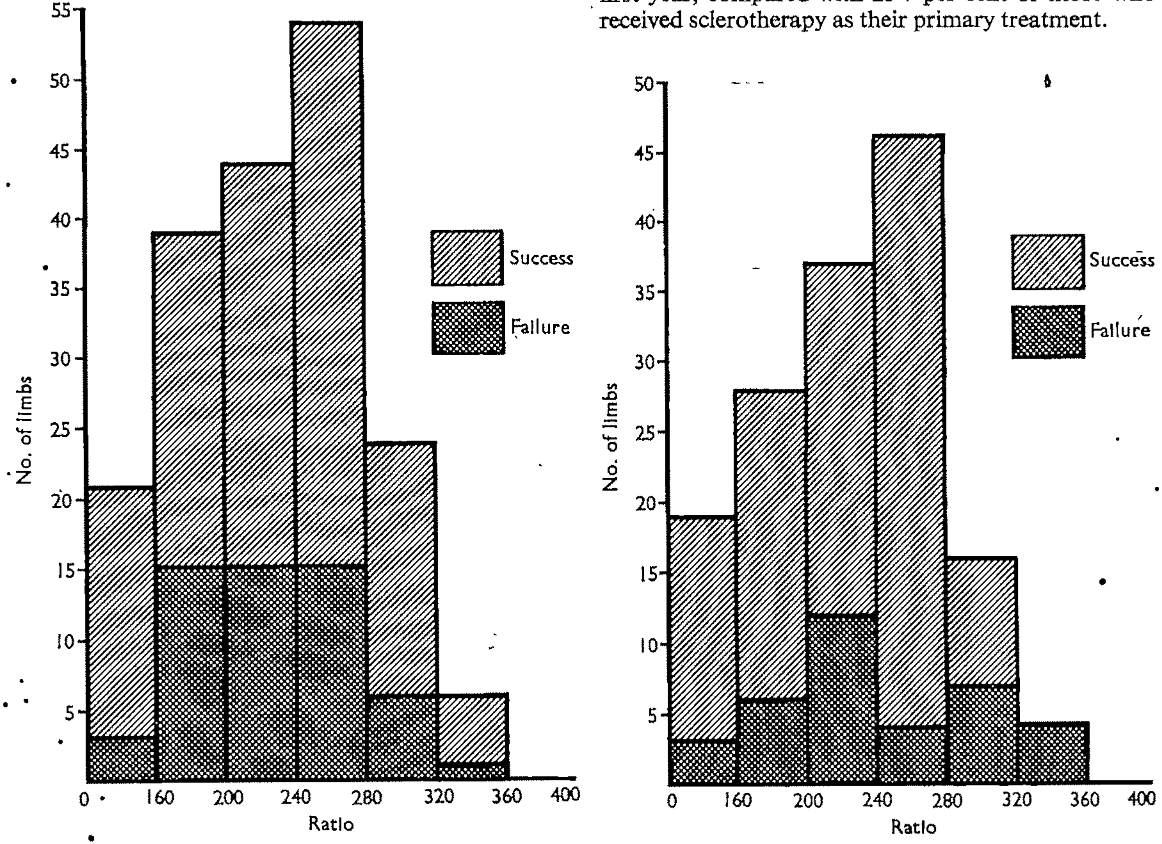
The results at the end of the first year are set out in *Table I.* The interpretation of this table is made difficult by the 75 limbs which, for a variety of reasons, were 'lost'. There are four possibilities:

1. All the 75 limbs which were 'lost' could have been successes.
2. All the 75 limbs which were 'lost' could have been failures.
3. The 49 limbs in the Fegan group which were 'lost' could have been successes but the 26 limbs in the operative group might have been failures.
4. The 26 limbs in the operative group which were 'lost' could have been successes and the 49 limbs in the Fegan group which were 'lost' could have been failures. *Tables II* and *III* show the calculation of χ^2 for each of these four possibilities.

It will be seen that except for the last contingency where all the 26 limbs in the operative group which were 'lost' are successes, and all the 49 limbs in the Fegan group which were 'lost' are failures, the Fegan method is superior to the operative method with values for P of less than 0·01. In the fourth permutation the two methods are equal in value. It is likely, therefore, that the initial response of varicose veins to compression-sclerotherapy is better than that to operation.

Table IV sets out the results at the end of the second year. They are of interest but of little value. They are of interest because they suggest that performing an operation before administering a course of sclerotherapy does not improve the results of sclerotherapy on its own. However, they are of little value because the efficiency of the follow-up during the second year fell from 85·1 to 66·9 per cent, the number of limbs 'lost' increasing from 75 to 166.

Table V shows an attempt to discover if pati'two whose varicose veins were mainly due to incompetents at the sephenofemoral junction, judged by the ence tourniquet' and calf exercise tests, ought to be treated primarily by operation. This is not the case; 49·6 per cent of the limbs on which a long saphenous stripping was done required Fegan injections at the end of the first year, compared with 23·7 per cent of those who received sclerotherapy as their primary treatment.



a *b*

Fig. 1. Results of sclerotherapy in relation to the configuration of the limbs. The limbs with the most slender thighs are represented by the column on the far left: those with the most bulky thighs by the column on the far right. *a*, At the end of the first year the failures were not concentrated amongst those with fat thighs and short legs. *b*, Results at the end of the second year supports the view that good results can be obtained on fat short legs if enough care is taken with the technique.

Table IV: RESULTS AT THE END OF THE SECOND YEAR

Treatment	Total limbs	No. lost	Limbs examined		Additional treatment	
			No.	%	No.	%
Fegan	280	102	178	63·6	39	21·3
Operation	222	64	158	71·2	26	16·4

There is no statistical difference between the two methods. Nearly half of the patients in the operation group had received a course of injections at the end of the first year.

Table V: SITES OF MAIN VALVULAR INCOMPETENCE

Vessels needing treatment	Fegan	Operation
Long saphenous vein alone	184 (23·7%)	149 (49·6%)
Long and short saphenous veins	20 (45·0%)	12 (33·3%)
Long saphenous and leg perforating veins	9 (11·1%)	25 (28·0%)
Long and short saphenous veins with leg perforating veins	None	9 (33·3%)
Short saphenous vein alone	10 (30·0%)	None
Leg perforating veins alone	1 (0·0%)	1 (0·0%)
Hunter's canal perforating vein alone	7 (14·3%)	None

Percentages in parentheses are the proportion in each group needing additional treatment at the end of the first year.

Table VI: EFFECT OF SITE OF THE VARICOSITIES

Site of varicosities	Fegan	Operation
Both thigh and leg	121 (30·6%)	122 (51·6%)
Knee and leg	107 (20·5%)	71 (40·8%)
Thigh only	3	3

Percentages in parentheses are the proportion in each group needing additional treatment at the end of the first year.

Table VII: EFFECT OF PRELIMINARY OPERATION ON NUMBER OF INJECTIONS NEEDED

No. of injection visits	Primary Fegan injections, clinical trial limbs (%)	Postoperative Fegan injections	
		Clinical trial limbs (%)	141 'Extra' limbs (%)
1– 5	64·6	82·4	77·7
6–10	23·8	14·0	19·0
11+	11·6	3·6	3·3

Table VI records the results of operation and Fegan's method in relation to the site of the varicosities. Fewer limbs treated primarily by sclerotherapy required additional treatment at the end of the first year than those operated upon, irrespective of site.

Fig. 1 analyses Fegan's (1963) opinion that obesity makes it hard to get a good result with sclerotherapy because maintaining the required compression is extremely difficult. This problem was tested by subtracting the circumference of the calf from that of the thigh and dividing the difference by the length of the limb. This measures the configuration of the limb. The figures show that although technically difficult, good results can be obtained on short limbs with very fat thighs.

Finally, the possibility that fewer injections would be needed per limb if a preliminary operation had been carried out was examined. This was suggested more than 20 years ago (McElwee and Maisel, 1947), but Fegan (1963) denies it.

In 1968 Reid and Rothnie reported from Reading a series of 974 patients (1358 limbs) treated by sclerotherapy with encouraging results. Now, for about 10 per cent, where the whole limb is involved from the groin to the ankle at a high pressure, limited surgery is carried out on a 'short-stay' basis prior to sclerotherapy (Rothnie, 1973).

Table VII details the number of visits for injections paid by the patients who were treated primarily by Fegan's method and by those who, having been operated upon, needed injections for residual or recurrent varicosities. The results support the opinion that a preliminary operation reduces the number of injections required subsequently. The results in a further 141 limbs, which were all operated on before the start of this trial and all needing Fegan injections for residual and recurrent varicosities, also support this view.

Conclusions

1. The initial response of varicose veins is better if Fegan's method is used than if they are operated upon.
2. Fegan's method is not contra-indicated by primary saphenofemoral incompetence or by fat thighs provided that, in the latter case, great care is taken with the technique.
3. Which method is better in the long run may never be known owing to the great difficulty of maintaining the efficiency of the follow-up for more than a short time.
4. It is likely that preliminary operation reduces the number of injections required subsequently.
5. The policy of treating varicose veins initially by Fegan's method will probably save money, beds and theatre time, without any detriment to the patient.

Secondary involvement of the penis by rectal cancer

B. I. REES*

SUMMARY

Two cases of metastasis to the penis from a primary rectal carcinoma are described. The clinical features, treatment and prognosis together with the probable modes of metastasis are discussed. All previously reported cases of penile metastasis from the rectum are reviewed.

It is suggested that contrary to previous reports the prognosis is not uniformly poor and hence a more aggressive attitude to treatment should be adopted. Metastatic lesions in the penis should also be considered as a cause of urinary obstruction following abdominoperineal excision of the rectum.

SECONDARY carcinoma of the penis is rare. Abeshouse and Abeshouse (1961) collected 138 cases from the literature and added 2 cases of their own. The primary sites of origin are in order of frequency: genitourinary 75 per cent, gastro-intestinal 18 per cent and other sites 7 per cent. The first case of metastasis to the penis from a primary rectal neoplasm was reported by Eberth in 1870. Since then only a further 18 authenticated cases have been recorded in the literature and only one report can be found in the British literature. Two further cases are reported here, both of which followed abdominoperineal excision of the rectum and both presented with perineal pain and urinary obstruction.

Case reports

Case 1: A 41-year-old male had an abdominoperineal excision of the rectum for a low rectal carcinoma in May 1971. There was no evidence of metastasis at operation. Postoperatively he made a good recovery although the perineal wound was slow to heal. Histological examination of the specimen (*Fig.* 1) showed a well-differentiated adenocarcinoma which had invaded the tissues outside the bowel wall, and tumour was found in the lymph nodes along the vascular bundles.

The patient remained well until March 1972, when he had recurrent episodes of ureteric colic and also pain in the perineal scar. The ureteric colic settled after the passage of a stone and an intravenous pyelogram at this time was normal. However, pain in the perineal scar was continuous and severe so that the scar was excised in September 1972. Histology of this specimen was not obtained.

He remained moderately well until April 1973, when he developed hesitancy of micturition, a poor stream and passage of small amounts of urine. This culminated in an episode of acute retention which was treated by catheterization. When the catheter was removed urine was passed spontaneously. A repeat intravenous pyelogram was normal.

In July 1973 cystoscopy revealed urethral stenosis in the urethral bulb. During dilatation of the stricture a large indurated area was felt in the corpora cavernosa. The dilatation resulted in some transient improvement, but 2 months later he again developed acute retention of urine. At this time, when the prepuce was retracted, there were four painless nodular swelling on the glans penis. The body of the penis was hard but there was no true priapism and the inguinal glands were not palpable. Catheterization and urethral dilatation were performed. Excision biopsy of the nodules showed adenocarcinoma compatible with metastasis from the rectum (*Fig.* 2).

The patient was commenced on 5-fluorouracil. After a week of this, an attempt at removal of the catheter was unsuccessful. At present he is alive with an indwelling catheter 33 months after his original abdominoperineal excision and 8 months after penile metastases were diagnosed.

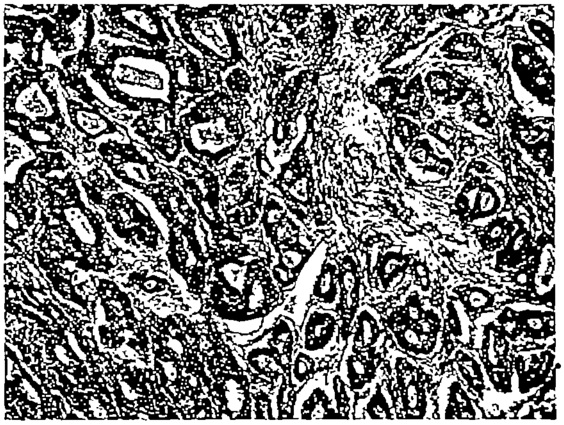

Fig. 1. *Case* 1. Histological section showing primary adenocarcinoma of the rectum.

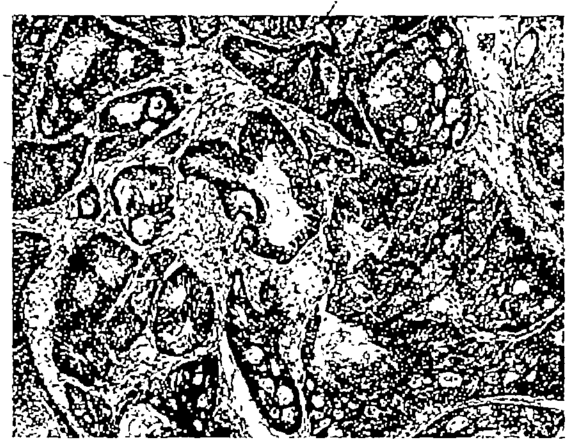

Fig. 2. *Case* 1. Histological section showing secondary adenocarcinoma of the penis.

Case 2: A 71-year-old male had an abdominoperineal excision of the rectum for carcinoma in May 1970. There were no secondary deposits at operation. The histology showed well-differentiated adenocarcinoma which had extended through the serosa and had involved the lymph nodes.

The patient made a good recovery and was well for 2½ years. until November 1972, when he developed pain in the perineal

NS, Not stated.

scar. A biopsy of the scar was performed and the histology showed adenocarcinoma compatible with an origin from the rectum.

After this procedure he developed acute retention of urine and required catheterization. In December 1972 a cystoscopy showed a hard shelf in the prostatic urethra and a trabeculated bladder. A transvesical prostatectomy with V resection of the bladder neck was performed. Histology of the bladder neck showed adenocarcinoma compatible with an origin from a primary large bowel tumour.

Three weeks later the perineal scar with the recurrence was widely excised. The tumour involved the perineal skin and bulbar urethra and extended deeply into the pelvis. The tumour was dissected from the urethra as far as the bulb of the penis but thereafter it was fixed and infiltrating. The perineum healed, but in April 1973 the patient again developed acute retention of urine. Urethroscopy showed a tight stenosis of the bulb which was solid with tumour and could only be dilated with difficulty. The patient was treated by a course of palliative radiotherapy to the pelvis with a marked improvement and spontaneously began to pass urine.

Four years after the abdominoperineal excision of rectum the patient is in good health and passes urine satisfactorily.

Discussion

The low frequency of occurrence of penile metastasis is surprising in view of the rich vascularity of the penis and its proximity to the rectum, bladder and prostate which are common sites of malignancy.

When penile metastases do occur they may present as either solitary or multiple nodules on the glans or in the body, or as solid infiltration of the corpus cavernosum, as in *Case* 2.

The previously reported cases of secondary carcinoma to the penis from a primary rectal carcinoma have been reviewed and the relevant data are shown in *Table I*. The symptoms reported include priapism, oedema of the penis, perineal pain and urinary retention. The urinary retention is probably due to compression and distortion of the urethra by secondary deposits. This view is shared by Selikowitz and Olsson (1973), who reported 2 cases of urinary retention due to urethral metastasis.

The methods of treatment have included local excision of metastasis, total penectomy, irradiation and the use of cytotoxic drugs. The number of cases is too small to state that any one method is superior to another.

It has been generally accepted that when secondaries have been identified the prognosis is poor, most patients being dead within 1 year. However, Cattell and Mace (1951), Boyd (1954) and Tagart (1967) have reported patients surviving 9, 6 and 5 years respectively after treatment of the penile metastasis. Two out of 3 of the long term survivors had radical amputation of the penis. The 2 cases described here are still alive 8 and 18 months after the penile metastasis appeared. They pose difficult management problems and perhaps a more aggressive attitude in the initial treatment of the penile metastasis, e.g. penectomy, would have improved the prognosis and made subsequent management easier.

The mechanisms of spread to the penis have been fully discussed by Paquin and Roland (1956); they include direct extension, spread by instrumentation, retrograde venous spread, direct arterial extension, retrograde lymphatic spread and paradoxical embolism. In the 2 cases reported here the most likely mechanism would appear to be direct extension since both patients had low rectal tumours and both had perineal recurrences. Stein and Hantsch (1937) considered that direct spread resulted from tumour extension into the corpus cavernosum via the ischiorectal fossa through the junction of the deep and superficial triangular ligament with Colles's fascia into the superficial perineal space.

Urinary retention occurring after abdominoperineal excision of the rectum is a well-recognized complication (Watson and Williams, 1952). The list of causes includes prostatic hyperplasia, autonomous neurogenic bladder, urethral stricture and postoperative malalignment of the bladder neck and urethra. The 2 cases reported emphasize that penile metastasis should be included in the differential diagnosis of urinary retention occurring after abdominoperineal excision of the rectum for carcinoma.

Acknowledgements

I wish to thank Mr G. Davies and Mr B. Peeling for permission to present their patients and also Mr P. Bolton for his advice.

Reviews and notices of books

Nontoxic Goiter. Concept and Controversy

Joel I. Hamburger, MD, FACP, Michigan. 235×160 mm. Pp. 222+x. Illustrated. 1973. Springfield, Ill.: Charles C. Thomas. $9.75.

This short book of about 200 pages which can be read in one or two evenings is a mine of practical information on the handling of thyroid disease excluding hyperthyroidism. It is written by a very busy practising thyroidologist who has already a similar book on hyperthroidism to his credit, published 5 years ago.

The book opens with a healthy critique of thyroid scanning, which puts it in its proper perspective, and then discusses non-toxic goitre, propounding the theory that if there is no goitre there is almost certainly no hypothyroidism. There is a review of thyroiditis, and then a good clinical approach to the problem of the thyroid nodule. The final six chapters are primarily concerned with thyroid cancer in all its aspects and it is interesting that the experience of the author is a little different from that in this country. Few would argue with his appraisal of the place of surgery and how far the operation should be extended. His experience of radioactive iodines has been on the whole rather disappointing, and his insistence on allowing the patient to develop hypothyroidism over 6 weeks, in order to obtain maximum uptake of isotope in the secondaries, is unkind to the patient though undoubtedly effective. His method of diuresis does not find many followers on this side of the Atlantic.

This is a very useful practical guide to the handling of patients with thyroid cancer and though didactic in presentation, the author is willing to support his line of action with good reason. As with all Thomas books the production is lavish and the price high by British standards.

SELWYN TAYLOR

Lectures on Methodology of Clinical Research

Max Hamilton, MD, FRCP, FRCPsych., FBPS, Wakefield. Second edition. 220×140 mm. Pp. 197+x. Illustrated. 1973. Edinburgh: Churchill Livingstone. £5.

Since Professor Hamilton's work deals with logic and the philosophy which should motivate and guide the aspiring research worker, that is how the lecture series start. Subsequent lectures deal with the nuts and bolts of statistical analysis, clearly explained and expounded. There is even a section on 'writing-up' and style, in which the prospective author is adjured to avoid popular and fashionable slang; what a pity that 'methodology' and 'experimentation' appear in the title and chapter headings—a bad example to the beginners but understandable since they are catchwords used in psychiatry and other subjects (or should one say 'disciplines'?) Nevertheless, this is a thoroughly readable and useful work which though written by a psychiatrist is applicable to any subject.

BRYAN N. BROOKE

Retinal Detachment. The Essentials of Management.

Hector B. Chawla, Chicago. 185×125 mm. Pp. 74. Illustrated. 1974. Edinburgh: Churchill Livingstone. £1·75.

It is difficult to know to whom this book is directed as an instruction in retinal detachment, while secondary detachment of the retina is virtually unmentioned. The short text contains many monochromatic drawings (understandably so because of the high expense of colour illustrations). Many surgeons would dispute the statements that retinal surgery should be carried out in specialist centres and that indirect ophthalmoscopy is the foremost basic skill—most surgeons would admit to the discovery of causal retinal tears with the aid of a direct ophthalmoscope which had been unnoticed by indirect ophthalmoscopy.

The text and illustrations leave much to be desired, being inadequate for the qualified surgeon and for the trainee about to prepare for higher examinations, although for a beginner in ophthalmology the book is a good introduction. Perhaps because of its brevity, the book leads the reader along too limited and selected channels of treatment, for example, the impression that air injection is therapeutically of paramount importance. There are many surgeons who repeatedly replace primary retinal detachments without the help of air. In the section on encircling bands the text leaves the reader completely ignorant on the correct positions and tension for tying the band, while it should be recognized that circumferential buckling at the equator does not necessarily produce retinal folds.

The section on anterior segment ischaemia seems to be too brief and, especially for the learner, contains insufficient information on its recognition and management.

Throughout, the book leaves too many questions and advocated therapeutic measures open for dispute, albeit that the treatment of retinal detachment is so varied. When planning future editions of this volume the author should seriously consider expanding the text to cover the subject more fully.

IAN M. DUGUID

Grundlagen der Nachsorge nach chirurgischen und urologischen Eingriffen

G. Jorns, Arnstadt, W. Remde, Potsdam, and H. Gerhard, Arnstadt. 220×155 mm. Pp. 280. Illustrated. 1974. Berlin: VEB Verlag Volk und Gesundheit. M.16.

This book on the fundamental principles concerning post-operative care covers a wide range of surgery. Somewhat surprisingly, cardiac surgery is discussed in one of the earlier chapters. The authors discuss postoperative management and the book is full of helpful advice even if basic physiological principles are scarcely mentioned. There are few illustrations and the appliances shown for the postoperative management of colostomies appear rather outdated by British standards.

The importance of rehabilitation in relation to an early return to work is stressed throughout.

H. B. ECKSTEIN

Therapeutic Aspects of Nutrition

Edited J. H. P. Jonxis, MD, H. K. A. Visser, MD, and J. A. Troelstra, MD. 230×160 mm. Pp. 344+xii. Illustrated. 1973. Leiden: H. E. Stenfert Kroese. 64P.

This excellent book contains the papers presented at the Fourth Nutritional Symposium held in Groningen in May 1973, and its rapid publication is most welcome. Whereas previous symposia have concentrated on the physiology and pathology of the newborn, the emphasis in this volume has shifted, with more discussion of nutritional principles and problems in the treatment of patients in hospital. There is still, however, a great deal of emphasis on the clinical difficulties of feeding the sick neonate and infant.

The book is divided into three sections which deal with physiological aspects of nutrition, the use of synthetic diets and parenteral nutrition respectively. The first section contains a series of authoritative but somewhat theoretical reviews of energy, water and salt requirements, protein, carbohydrates and linoleic acid as nutrients and some nutritional aspects of trace elements and vitamin D and E metabolism.

Of greater surgical interest is the second section, with a discussion of the use of elemental diets in the preoperative preparation of patients for abdominal surgery and in the management of malabsorption problems, intestinal fistulas and inflammatory bowel disease. The need to increase the elemental diet slowly for maximum benefit is stressed.

The third section is dominated by the care of the paediatric case, but it is suggested that supplementation of energy intake with 800 kcal/day of fat intravenously in adults can help with both energy balance and well-being and lead to an improvement in appetite. More practical details in this and the other sections would have been helpful but there is a great deal of interest in this review.

W. P. T. JAMES

Rontgenuntersuchung der Brust. Technik Diagnostik Differentialdiagnose Ergebnisse.
W. Hoeffken and M. Lanyi. 290 × 205 mm. Pp. 344 + viii, with 489 illustrations. 1973. Stuttgart: Georg Thieme Verlag. DM.148.

THIS book is devoted to radiological investigations of the breast. The first few chapters describe in detail the radiographic machinery required and the techniques used. The radiological appearances of the breast in specialized plain films, following contrast injection, and on arteriography are illustrated and compared with clinical photographs and, where relevant, with photomicrographs. It is clear that radiology of the breast has become a standard diagnostic technique. All conceivable pathological processes of the breast are discussed and described in relation to the radiological changes. Other methods of investigations such as thermography are detailed in an appendix.

The book is full of superb illustrations including many colour photographs of the clinical appearance of the breast which are invaluable for comparing with the radiographic appearance. There is no doubt that this book will become one of the standard volumes concerning radiology of the breast and it is undoubtedly of considerable interest to both radiologists and surgeons who specialize in treating diseases of the breast.

H. B. ECKSTEIN

The Management of Trauma
Edited Walter F. Ballinger II, MD, Robert B. Rutherford, MD, and George D. Zuidema, MD. Second edition. 250 × 175 mm. Pp. 795 + xiv, with 296 illustrations. 1973. London: W. B. Saunders Company. £12·40.

The most obvious difference between the first and second editions of *The Management of Trauma* is that the cover is now blue instead of green. In matters of detail there are a few spelling mistakes and the type face and headings are clearer. There are 20 fewer pages of text, and although the number of chapters is the same as before, radiation injuries, the role of the internist and psychological aspects have been omitted; vascular injuries have a chapter of their own and the management of fractures is covered in two chapters. A very useful chapter on mass disasters has been added.

Generally, the book has been brought well up to date; some chapters have been entirely rewritten and many others expanded or revised. The chapter on pathophysiology of trauma and shock contains a sound critical review of the work of Shires, and that on the treatment of shock is refreshing in its simplicity of approach, its invitation to look at the patient as well as records and for the fact that it refers to the work of Grant and Reeve and Ruscoe Clarke.

Renal failure and cardiopulmonary resuscitation and analgesia are described for surgical readers, but there is no mention of entonox in the latter chapter.

Injuries of the neck now include a section on the management of injuries of the large vessels in the neck. In the chapter on tracheostomy British readers will be surprised to find no mention of the Björk flap, and in the chapter on abdominal injury the experience of Ashton Miller and Mitchell with rupture of the urethra goes unrecorded. There is an unusually helpful account of the use and interpretation of plain radiographs of the injured belly.

There is much of practical value in this book but there is a curious variation from careful attention to detail, such as occurs in the section on wounds in the initial management of injuries of the lower limb, to a brief and general account, such as that of the injuries of nerves and tendons. There is, for example, now no mention of rupture of the tendo Achillis. The injured hand is dealt with in far too little detail to be of much assistance in matters of diagnosis and treatment, and it appears that news of the groin flap has yet to reach the United States. It seems also that orthopaedic surgeons have so far resisted invasion by A.O.

In summary, it is difficult to know for whom the editors intended this book; the quality is too uneven for it to satisfy the examination candidate on the one hand, or the perplexed surgeon confronted by a difficult case following injury on the other. One recognizes the immensity of the editors' task and the difficulty in striking a satisfactory balance between essentially practical guidance and comprehensiveness within a reasonable compass. Editors the world over will surely sympathize with the three men that have produced the two editions of this book. They have made quite striking changes and one may hope that in future editions there will be a more successful endeavour in pursuit of balance. Although the chapter on psychological aspects was not one of the most successful in the first edition it is a pity that the subject has been abandoned; perhaps this is because the title of the book refers only to trauma and not to those that suffer injury.

P. S. LONDON

Renal Histopathology. A Light Microscopy Study of Renal Disease
Robert Meadows, MD, FRCPA, Adelaide. 283 × 223 mm. Pp. 363 + xii. Illustrated. 1973. London: Oxford University Press. £14.

THIS book describes the morphological changes of renal disease as seen with the light microscope, drawing upon the newer techniques of immunofluorescence and electron microscopy only in so far as they help to elucidate light microscopic appearances. It concentrates mainly on renal biopsy material, the approach to which is dealt with admirably in the preface, and includes a useful chapter on technique to help the reader gain the maximum information possible from the material available.

The book is in two parts. Part 1 describes the individual structures of which the kidney is composed and their response to various disease processes. Part 2 deals with specific diseases as they affect the kidney as a whole. This approach inevitably leads to some repetition but is of value in stressing the importance of systematic assessment in building up a composite picture of the pathological changes present before considering diagnosis. One disadvantage is that, when using the book for reference purposes, more than one chapter may have to be consulted to cover a single subject.

The author's personal experience and the literature on the subject are well integrated and the illustrations are numerous and very adequate. Of special value is the use of serial biopsies in the individual patient to trace the natural course of a disease or to study the modifications due to therapy.

On some subjects detail is lacking. For example, the later stages of idiopathic membranous glomerulonephritis are not described. Nevertheless, the book is fairly comprehensive and can be recommended to both histopathologists and renal physicians.

KATHERINE M. CAMERON

Basic Clinical Surgery for Nurses and Medical Students
Edited John McFarland, Liverpool. 222 × 140 mm. Pp. 767 + xviii. Illustrated. 1973. London: The Butterworth Group. £2·20.

THE idea of a book on basic clinical surgery being suitable for nurses and medical students is at first difficult to accept. One instinctively suspects that it would contain too much for the nurse and too little for the medical student. From the nursing point of view there is an excellent all-round cover of the subject, the inclusion of a chapter on the care of children with congenital disorders being particularly welcome. Details of investigations and patient care not generally included in surgical nursing books are invaluable. The sketch diagrams are excellent, making it an ideal quick reference book, useful for all grades of students and trained nursing staff. From the point of view of the medical student starting his clinical work it provides a useful introduction and practical guide but it is not enough for his final examinations. It is well produced, clearly written and wastes no words.

IAN MCCOLL

Reviews and notices of books

Orthopaedic Surgery and Traumatology

Edited R. De Marneffe and E. Vander Elst. 245 × 175 mm. Pp. 1155+xxiv. Illustrated. 1974. Amsterdam: Elsevier Excerpta Medica North Holland. D.Fl. 275.

ONLY to translate, collate and edit more than 400 papers in half a dozen languages is a considerable achievement. To have done so in such a way as to make the material readily available and the whole book eminently readable is a truly remarkable editorial feat.

The book comprises the proceedings of the Twelfth Congress of the International Society for Orthopaedic Surgery and Traumatology (SICOT) which was held in Tel Aviv in October 1972, and there is to be found in its 1200 pages some reference to every item of interest to contemporary orthopaedic surgeons. To achieve the objective of such a report, very careful indexing and cross-reference is essential and this has been neatly and adequately achieved. It is interesting to read how global are the problems which confront orthopaedic and accident surgeons, and fascinating to catch a glimpse of the thought and practice of surgeons far afield and how they deal with the problems which confront all of us. Important sections will be found on artificial joint replacement and malignant tumours of bone, and of subjects so diverse as, for example, the use of Chymopapain in the treatment of lumbar disk disease, spondylolisthesis, haemostatic deficiency surgery—the list is endless.

All those engaged in the surgery, clinical investigation or laboratory research of disease affecting the locomotor system are well advised to have this volume for easy reference on the library shelf. The book cannot, of course, be read through from cover to cover, nor is it intended to be. Like a good dictionary it will undoubtedly find episodic and invaluable use. The quality of paper, print and illustrations is faultless. A monumental editorial task has been brilliantly achieved.

L. KESSEL

The Surgery of the Central Nervous System

D. W. C. Northfield, MS, FRCS, FRCP, London. 254 × 205 mm. Pp. 884+xi. Illustrated. 1973. Oxford: Blackwell Scientific Publications. £22·50.

MR NORTHFIELD is a link, and a very lively one, between present day neurological surgery and the founders of the subject in this country almost 50 years ago. His experience is vast and his knowledge of both the practical and academic aspects of the subject is unrivalled. All of us, in particular those in training, owe him a great debt for the care and industry that have gone into the production of this account of neurological surgery. At a time when multiple authorship is almost obligatory, this beautifully produced volume must be unique. It has the great virtue of presenting a fair cross-section of informed opinion on any subject with the author's assessment based on his personal experience. It is comprehensive and authoritative with an excellent and apparently very accurate bibliography. The style is easy and, although it may not be everyone's idea of a bedside book, it is no exaggeration to say that it can be read for pleasure. I am in no doubt that it is by far the best available book on the subject in English, providing as it does a bridge between what textbooks there are and the scientific literature. A wider audience than that provided by neurosurgeons can be confidently expected amongst medical neurologists and physicians and surgeons to whom it can be recommended without reservation.

The relevant clinical neurology, histology and neuroradiological techniques are dealt with in detail, but wisely the author has refrained from an attempt to include details of operative technique. This does not mean that he does not express opinions on the type and scope of surgical procedures or the likely results of surgery, but he takes the view that technique is taught by apprenticeship and this restraint has limited to some extent the size and expense of the volume which, nevertheless, are still not inconsiderable. This book will prove a necessary addition to personal and departmental libraries.

JOHN HANKINSON

Current Practice in Orthopaedic Surgery. Volume 5, 1973

Edited James P. Ahstrom Jun., MD, Illinois. 255 × 180 mm. Pp. 308+ix. Illustrated. 1973. London: Henry Kimpton. £13·25.

IN this, the fifth annual volume of brief monographs on orthopaedic subjects of topical interest, much depends on the subject selected and the man to write it. Both choices by the editor have here been usually excellent though inevitably patchy.

The 'Management of Low Back Pain' by Ian McNab of Toronto is a superb short account of this problem. McNab has contributed much new knowledge to this field. However, his greatest contribution in this article is his succinct and beautifully clear and descriptive account of a complex problem. All who read this will learn.

'Arthroscopy of the Knee' by Robert Jackson of Toronto is a good survey of this new technique with some consideration of its advantages and limitations.

There are three contributions to the subject of total joint replacement, obviously an important and rapidly changing technical problem. All three are well worth reading.

Samilson has made some interesting observations on scoliosis in cerebral palsy, until now a neglected subject. DeWald reviews 'New Trends in the Operative Treatment of Scoliosis', an area of surgery undergoing dramatic changes with the new technical advances of the past decade or two. It is perhaps a rather dry matter-of-fact account with too little comment on the special indications and difficulties of the alternative methods.

There are in all eleven contributions, and the reviewer found all worth reading and a few outstanding.

J. I. P. JAMES

Recent Advances in Thrombosis

Edited L. Poller, Manchester. 212 × 146 mm. Pp. 227+ix. Illustrated. 1973. Edinburgh: Churchill Livingstone. £5·50.

TEN papers, seven from Europe and three from the USA, have been collected from those of eleven simultaneous sessions at the 1972 Congress of the International Society on Thrombosis and Haemostasis; the editorial policy was to choose from areas of active investigation. Personal distinction on the part of the contributors could well have been another factor in the selection, for the list includes many household names in this growing discipline. The fact that much of the material presented is more of a progress report than on new work in no way lessens its value. As a guide to the present state of knowledge, and the paths by which this has been reached, it cannot be faulted. The literature is presented with a wise and critical selectivity, and the reference value of the book is much helped by the excellent index. Among the many stimulating sections a few choose themselves for special mention: for example, Sevitt on the morbid anatomy of sites of origin, Vessey on the modern trend in epidemiology, Vermylen and colleagues on the role of the platelets, including the effect of aspirin and other active drugs, Prentice and McNicol on treatment by fibrinolysis and the editor himself on the effects of the contraceptive pill. Other chapters of equal merit make up a most interesting and valuable compact source of good reading and useful reference.

H. H. G. EASTCOTT

Tumors of the Extra-adrenal Paraganglion System (including Chemoreceptors)

George G. Glenner, MD, and Philip M. Grimley, MD, Maryland. 260 × 200 mm. Pp. 90. Illustrated. 1974. Washington: Armed Forces Institute of Pathology. $4·50.

THIS book is the latest addition to the well-known and authoritative *Atlas of Tumor Pathology*. Although written primarily for pathologists, it will be of value to surgeons who encounter any of the rare paraganglionic tumours. In addition to the excellent pathological descriptions, it contains a clear and concise account of the anatomical distribution, clinical features, differential diagnosis, endocrine activity and treatment of the paraganglionic tumours.

R. B. WELBOURN

Care of the Ostomy Patient

Virginia C. Vukovich, RNET, and Reba D. Grubb, Arizona. 227×150 mm. Pp. 138+xii, with 23 illustrations. 1973. London: Henry Kimpton. £2·35.

THE aims of this book are highly commendable. The increasing interest in the total care, support and rehabilitation of the ostomy patient is long overdue, and those concerned with these people should make every effort to spread this concept. The psychological trauma of facing up to a situation in which faeces are discharged on to the abdomen is great in itself, without the associated problems such as odour, leaking appliances and sore skin with which this group of people has to contend. Until quite recently the attitude has been that this is something that the patients must learn to live with! Any book, therefore, that promotes interest in this subject can only do good, and this one, in particular, is well planned, researched and written.

It covers the medical aspects for the reasons for creating a stoma and its practical care and management; also suggested educational programmes for teaching both experienced nurses and non-professionals who are interested in giving some service, supportive and practical, for these patients.

The section on practical management is clear and comprehensive; obviously there are differing opinions on specific treatments, such as using solvents on the skin, but anyone studying this book could learn some good principles.

The advice on counselling the patient before operation is especially good; this is sadly lacking still in many hospitals in this country and elsewhere, but is the most important step in helping the patient in the process of acceptance and rehabilitation.

On the educational side, the training programmes described may be suitable for the United States but the reviewer feels that they are not really geared to the needs of nurses in Britain. With smaller financial resources available these programmes tend to be more concentrated. If our own students are taught the necessity for giving support and information to these patients, and the basic problems and management of the stoma are understood, by involving them in as much active practical experience as possible during a course, combined with good lectures and discussions related to the subject, this should be sufficient.

In all, this book would be a welcome addition to any library used by people concerned with this group of patients.

BARBARA SAUNDERS

A History of the Army Medical Department. Volumes 1 and 2.

Lt-Gen. Sir Neil Cantlie, Late Director General, Army Medical Service. 240×160 mm. Volume 1: Pp. 519. Volume 2: Pp. 448. Illustrated. 1974. Edinburgh: Churchill Livingstone. £12.

THE traditions of our Medical Corps have always inspired pride. These feelings have been enhanced by this comprehensive, detailed and fascinating record of all that led up to and contributed to its formation, step by step. Progress continued in spite of the almost overwhelming military prejudice and ignorance.

Volume 1 (1660–1853) and Volume 2 (1854–1898) are meticulously supported by full lists of references. These volumes, especially Volume 2, should be of great interest to all surgeons and others concerned with the care of the sick and wounded. The author, with his experience as a surgeon and as a Director General of the Army Medical Service, proves his talents and quality as a critic, historian and writer. He held the reviewer's interest throughout, in spite of many repetitions in the first volume. To condense this very complete record to one volume would have sacrificed much of great value. Statistics and uninspiring reports are interspersed and enlivened by masterly descriptions of conditions and pen pictures of events vividly recorded by participants at the time. This is highlighted by the citations of the Victoria Crosses awarded.

Throughout this history the same military administrative, medical and surgical mistakes are repeated over and over again. With this readily accessible record, collected together in one place, along with authentic and interesting details unearthed from the past, they should not be repeated. Had the reviewer read this before the Second World War he would have been much wiser.

Useful guidelines for fighting future administrative battles, with strong support as in the past from civilian colleagues in the Royal Colleges and the BMA, will be found in these volumes. The blood of warriors has trained many surgeons.

R. A. STEPHEN

Chirurgie der Gegenwart. Volume 5

Edited Rudolf Zenker, München, Franz Deucher, Aarau, and Wilhelm Schink, Köln. 260×180 mm. Pp. 121. Illustrated. 1974. München: Urban & Schwarzenberg. No price given.

THIS is the orthopaedic volume of the new loose-leaf textbook of surgery. Apart from a large and relatively empty folder it includes the first 7 chapters. The first chapter by Professor Mau attempts to deal with all congenital abnormalities of the skeletal system, and the illustrations certainly suggest that the corrections of such abnormalities require a vast amount of ironmongery. The second chapter deals with the diseases of joints, while the third chapter is academic and discusses the development of arthritis. Other chapters deal with rheumatic disease, diseases of the intervertebral discs and all sinovial membranes.

It is noteworthy that some of the references quoted are as recent as 1973.

H. B. ECKSTEIN

1972 Surgery Annual. Volume 4

Edited Philip Cooper, New York, and Lloyd M. Nyhus, Illinois, 235×172 mm. Pp. 445+ix. Illustrated. 1972. New York; Appleton-Century-Crofts. $19.25.

A VARIED and variable volume. There is an excellent review on shock, but the treatment of venous thrombo-embolism contains no references to the excellent contributions from the United Kingdom in the past few years. The chapter on peptic ulcer illustrates closure of the duodenum in several diagrams, as well as photographs, which seems unnecessary in this kind of book. Curiously, the references on follow-up after vagotomy omit the papers by Goligher and his colleagues. Chapters on the short gut syndrome and the significance of ileal resection are complementary and well written, but elsewhere the book is less thorough and the references are sometimes limited and inadequate.

This book is for the library, and most British surgeons will consult it there.

C. G. CLARK

Klinische Urologie. Ein Lehrbuch.

Edited C. E. Alken and W. Staehler. 265×180 mm. Pp. 611+xvi. Illustrated. 1973. Stuttgart: Georg Thieme Verlag. DM.148.

THIS is a new textbook of urology in which 32 leading urologists and others from Germany, Austria and Switzerland have collaborated. Alken's introductory chapter stressing the need for expansion of urology in Germany should provide useful information for the British Association of Urological Surgeons! Every conceivable aspect of urology is covered and the book includes chapters on urology in the female, renal hypertension and renal failure. There is even a chapter on the assessment of disability in relation to urinary tract disease and a rather fascinating summary of the history relating to urology going back to 2000 B.C. Paediatric urology has been covered extensively by R. Hohenfellner and his colleagues.

The volume is illustrated throughout by excellent reproductions of radiographs, some very good line diagrams and 3 pages of well-reproduced colour illustrations. As each chapter has been written by an authority on the subject, it is perhaps reasonable that the references quoted are minimal and are largely restricted to the German literature.

The volume is beautifully produced and completely up to date and should be of considerable interest to any urologist who can understand German.

H. B. ECKSTEIN

Book notices

[The Editorial Committee acknowledge with thanks the receipt of the following volumes. A selection will be made from these for review, precedence being given to new books and to those having the greatest interest to our readers.]

Hyperparathyroidism

Edward Paloyan, MD, Illinois, Ann M. Lawrence, MD, Illinois and Francis H. Straus, MD, Illinois. 233×158 mm. Pp. 222+x. Illustrated. 1973. New York: Grune & Stratton Inc. $16.00.

Mammography, Thermography and Ultrasonography in Breast Disease (Radiology in Clinical Diagnosis Series)

K. T. Evans and I. H. Gravelle. 210×127 mm. Pp. 148+x. Illustrated. 1973. London: Butterworths. £4·45.

Anaesthesiology and Resuscitation. Ketamin.

R. Frey, Mainz, F. Kern, St Gallen, and O. Mayrhofer, Wien. 229×152 mm. Pp. 464+xv. Illustrated. 1972. New York: Springer-Verlag. $25.20.

Anaesthetics, Resuscitation and Intensive Care

W. Norris, Glasgow, and D. Campbell, Glasgow. Fourth edition. 250×140 mm. Pp. 289+xii. Illustrated. 1974. Edinburgh: Churchill Livingstone. £2.

The Nature of Cancer. Volume 1.

Manu Kothari and Lopa Mehta. 245×185 mm. Pp. 902+xxx, with 132 illustrations. 1973. Bombay: Kothari Medical Publications. £12.

A Companion to Surgical Studies

R. Nigam, New Delhi. 240×170 mm. Pp. 623. Illustrated. 1973. New Delhi: Academic Books Limited. Rs.22.

Uveitis, Immunologic and Allergic Phenomena

R. Campinchi et al. Translated, revised and indexed by Bruce Golden, Johannesburg, and Marlette M. Givioset, Iowa. 254×171mm. Pp. 818+xvi. 1973. Springfield, Ill.: Charles C. Thomas. $39.50.

DuVries' Surgery of the Foot

Verne T. Inman, San Francisco. Third edition. 260×184 mm. Pp. 567+xvi. 1973. London: Henry Kimpton. £12·35.

1973 Pathology Annual

Series editor, Sheldon C. Sommers, New York. 241×171 mm. Pp. 479+viii. 1973. New York: Appleton-Century-Crofts. $18.50.

Biomedical Materials Symposium No. 4. Materials and Design Considerations for the Attachment of Prostheses to the Musculoskeletal System.

Edited S. F. Hulbert, S. N. Levine and D. D. Moyle, South Carolina. 235×152 mm. Pp. 465+xii. 1973. Chichester: John Wiley & Sons Ltd. £9.

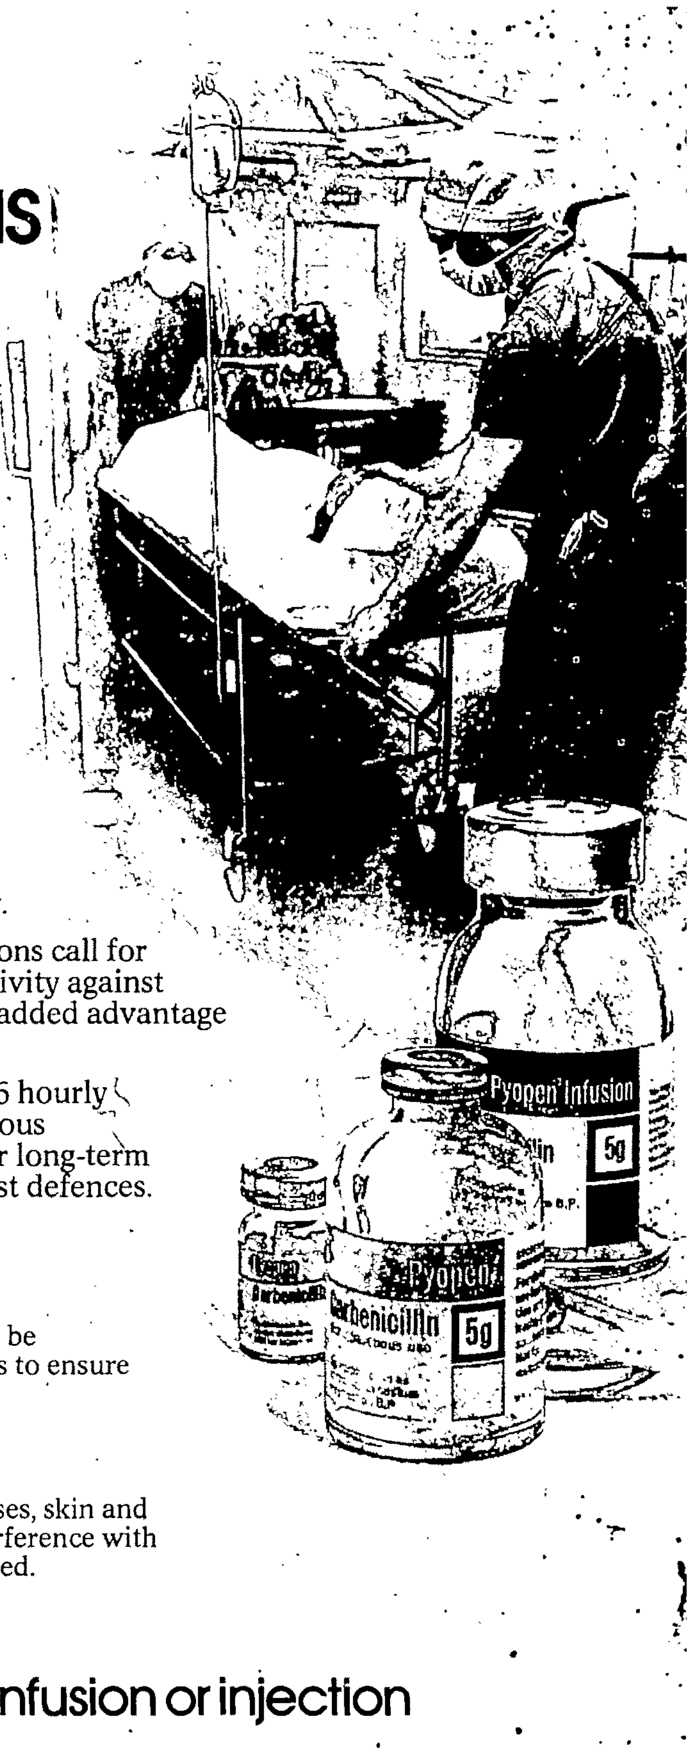
Physician's Handbook

Edited Marcus Krupp et al., California. Seventeenth edition. 178×108 mm. Pp. 727. 1973. California: Lange Medical Publications. $6.50.

A System of Orthopaedics and Fractures

A. Graham Apley. 206×178 mm. Pp. 540+x. 1973. London: The Butterworth Group. £8·80.

When pseudomonas threatens...



Pyopen

The skill of the surgical team, hours in the theatre, the most advanced techniques in the world . . . and infection can still throw the outcome into jeopardy.

Systemic pseudomonas or proteus infections call for Pyopen. Only Pyopen offers you good activity against these Gram-negative organisms with the added advantage of penicillin safety.

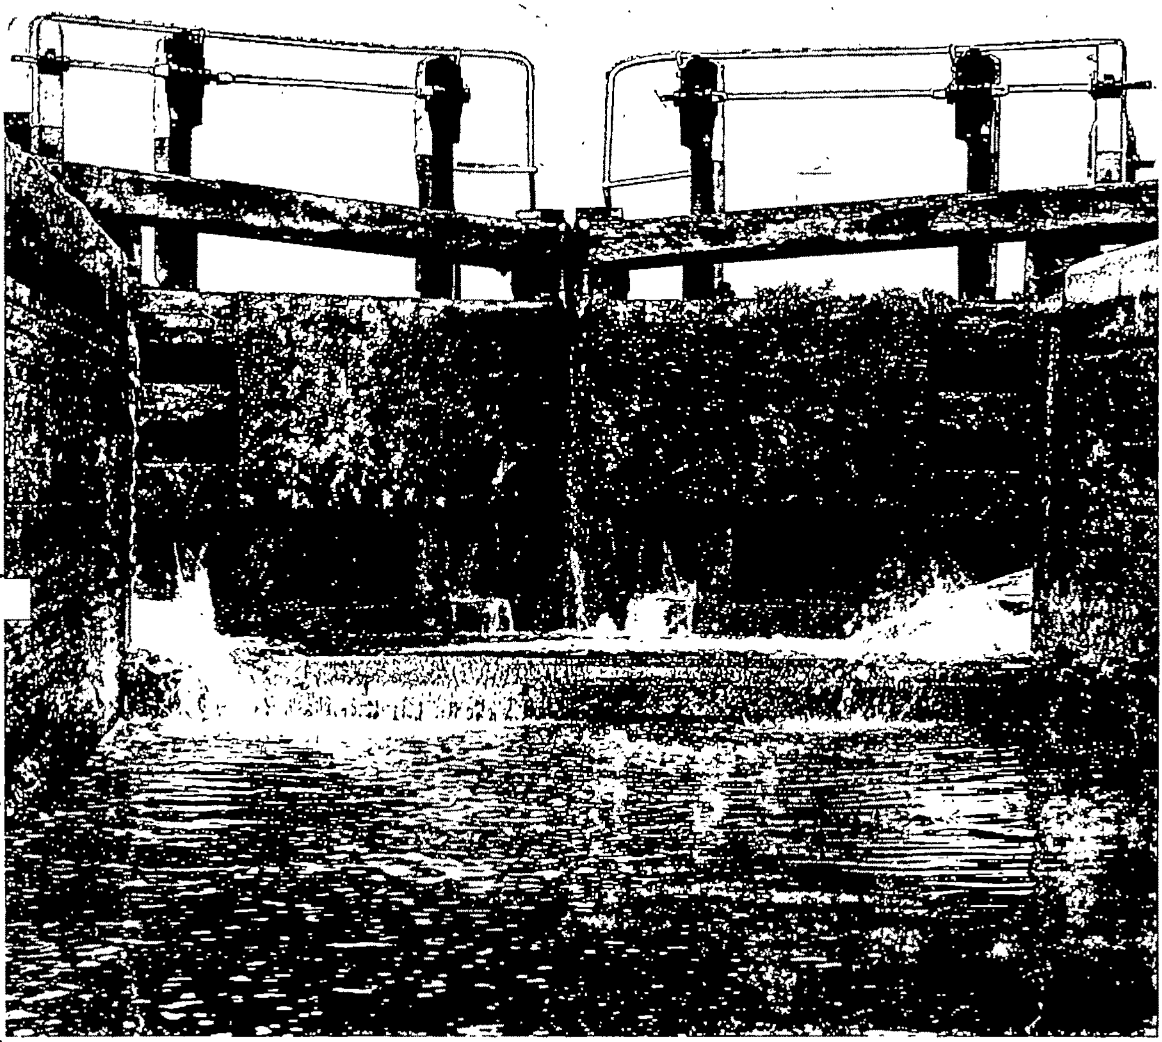
Intravenous Pyopen, at a dosage of 5g 4–6 hourly will rapidly control many of these dangerous infections. And Pyopen is also suitable for long-term therapy and for patients with lowered host defences.

Adult Dosage
5g I.V. 4–6 hourly.
In patients with renal impairment dosage may be reduced; monitoring is advisable in these cases to ensure adequate serum antibiotic levels.
Contra-indication
Penicillin hypersensitivity.
Side-effects
As with other injectable penicillins. In rare cases, skin and mucous membrane haemorrhages due to interference with normal clotting mechanisms have been reported.

Pyopen - by infusion or injection

Further information is available on request.
Pyopen* (carbenicillin sodium B.P.) is a British product originated by
Beecham Research Laboratories, Brentford, England. *regd.

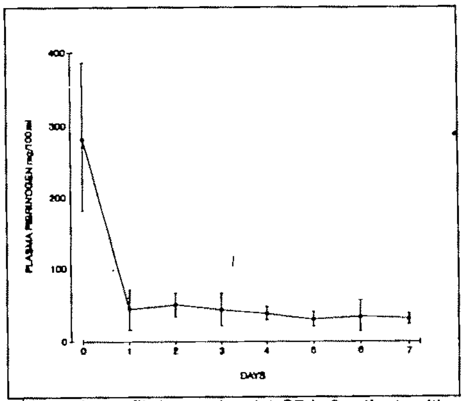
A new concept in the control of occlusive vascular disease



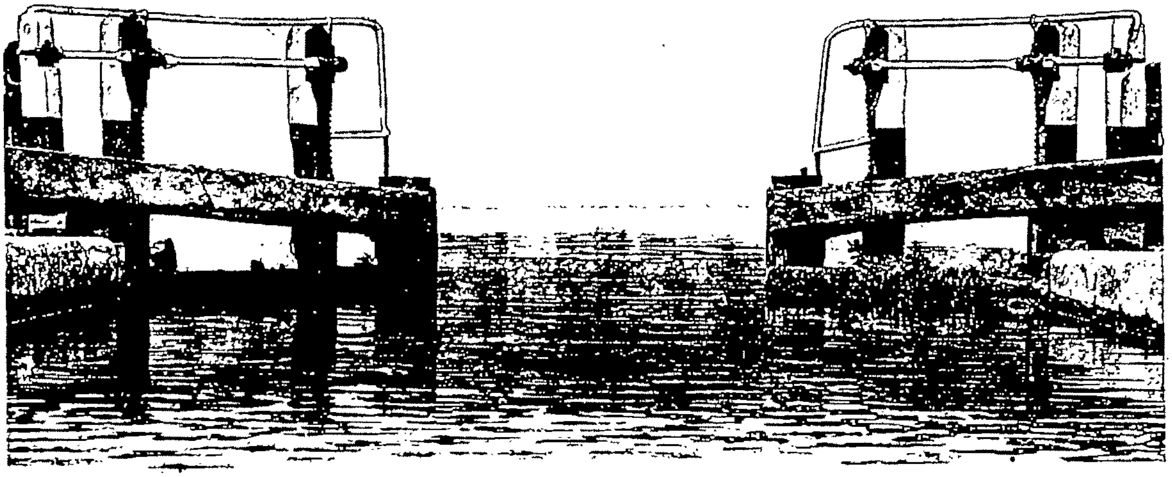
A unique drug is now available to the specialist for routine anticoagulant therapy, and to the researcher as an aid to the elucidation of thromboembolic disorders. Its name is Arvin.

Arvin reduces plasma fibrinogen to a level that maintains marked hypocoagulability without serious spontaneous bleeding complications. This desirable effect is achieved through the specificity of Arvin for fibrinogen—other clotting factors are unaffected.

This state of 'pure' defibrination has an important clinical place when prophylactic measures need to be taken in occlusive vascular disease, e.g. to prevent the formation and extension of thrombi and the dissemination of emboli.



Mean plasma fibrinogen level ± SD in 9 patients with venous thromboses. Arvin 2 units/kg body weight intravenously every 12 hours. From Pitney WR, (1971). Thromb Diath Haemorrh, *45*, 43.



Consistent features of Arvin therapy include an absence of thromboembolic events during treatment, absence of fibrinogen rebound and low incidence of rethrombosis after treatment has ceased. On withdrawal, plasma fibrinogen returns to haemostatic levels within 12 hours and to normal after 10-20 days. Thus, the changeover to oral anticoagulants is smooth and complication-free.

A consistent dose-effect relationship which ensures simple and precise control methods has been established for Arvin. On this basis, we can recommend this drug for a range of indications where controlled therapeutic defibrination is desirable.

For instance, deep vein thromboses, central retinal and branch vein thrombosis, priapism, pulmonary hypertension of embolic origin, embolism after prosthetic cardiac surgery and rethrombosis after thrombolytic therapy have been shown in clinical trials to respond well to Arvin.

To find out more about the unique Arvin concept specialists are invited to write to us for detailed clinical literature and prescribing information.

Nolvadex–a more acceptable approach to breast cancer treatment

Drug therapy is often both uncomfortable and distressing for the patient with advanced breast cancer. But now a more acceptable treatment is available for such patients, 'Nolvadex' (tamoxifen).

'Nolvadex' is an oestrogen antagonist. Whilst it is just as effective as other treatments, it has no hormonal properties. Virilization–common with androgens–is unknown; oedema, nausea and vomiting occur much less frequently than with oestrogens.

'Nolvadex' is taken as twice-daily oral doses. So treatment is simple as well as more acceptable.

Further information–including the results of U.K. trials with 'Nolvadex'[1,2] is available on request.

Fight cancer with a will

When testators ask your advice, please remind them of the urgent work of the Imperial Cancer Research Fund. In the Fund's up-to-date laboratories trained minds are using every weapon of modern science to fight all forms of cancer, including leukaemia.

Now one of the world's great research centres, the I.C.R.F. relies entirely on public support. The cancer problem *must* be solved. Please help now.

Patron:
H.M. THE QUEEN
President:
The Honourable Angus Ogilvy

Form of Bequest

I hereby bequeath the sum of..................pounds free of duty to the Imperial Cancer Research Fund, Lincoln's Inn Fields, London, WC2A 3PX for the purpose of scientific research, and I direct that the receipt of the Honorary Treasurer or Secretary shall be a good discharge for such legacy.

Please write for further information to: The Secretary, I.C.R.F. (Dept 164), PO Box 123, Lincoln's Inn Fields, London WC2A 3PX

"I Bring Peace"-73

"It is concluded that maintenance treatment of ulcerative colitis with sulphasalazine (salazopyrin) should be continued indefinitely unless contraindicated by side effects".[1]

The results of the above controlled trial carried out at the Nuffield Department of Clinical Medicine, Radcliffe Infirmary, Oxford are all the more welcome as earlier trials of cortisone[2] and prednisone[3] at standard dosages have shown them to be ineffective in reducing the number of recurrences of ulcerative colitis.

"Fortunately, Sulphasalazine tablets, 0.5 grams 4 times a day will prevent relapses in the majority of patients with colitis, and only a few patients cannot tolerate this relatively small dose, which can be continued indefinitely since we do not know when, if ever, it can be safely stopped".[4]

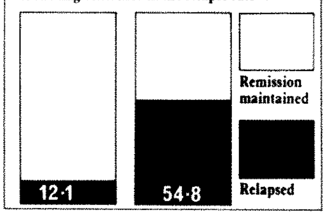
Salazopyrin (sulphasalazine) is available as the plain 0.5g. tablet, 0.5g. EN-tab and as an 0.5g. suppository. Literature and detailed information on Salazopyrin are available on request.

Salazopyrin is a registered trade mark.

Salazopyrin

– to be continued indefinitely

"A striking difference in the relapse rate".



"The patients who received dummy tablets had more than four times the relapse rate of those receiving sulphasalazine".[1] (Salazopyrin).

"Both groups of patients had been satisfactorily maintained for 1 – 5 years on Salazopyrin prior to the study, in which they took Salazopyrin or placebo for 6 months."

The Collaborators.

We have our own workshops where skilled craftsmen make Seward surgical instruments. Nothing less than ultimate perfection will satisfy them.

Our sales people's viewpoint is also important. They're in constant touch with the medical profession. So they know what is wanted – and why.

Then there's the surgeon. We never hesitate to ask a surgeon for his advice. After all, we make surgical instruments, and he uses them. So it's naturally beneficial to work closely together, for both of us.

It's true we have an enviable reputation at Seward for fast delivery of our instruments.

But when it comes to design, we take all the time it needs to get things right.

seward – the fast word in quality

EDITORIAL NOTICES

Original articles or reviews are invited and editorial communications should be addressed to the *Editorial Secretary, British Journal of Surgery, c/o John Wright & Sons Ltd., Bristol BS8 1EX.* Articles are accepted on the understanding that they are contributed to this Journal only, and that articles and their illustrations become the property of the Journal unless the authors state, before publication, that they reserve the right to themselves. Each article should be accompanied by an adequate summary, suitable for publication. Authors are asked to ensure that original illustrations are securely packed and adequately protected.

BUSINESS COMMUNICATIONS should be addressed to *John Wright & Sons Ltd., British Journal of Surgery, Bristol BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery.*

BINDING.—Handsome Cloth Cases may be obtained for binding Vol. 60. Case, £2·00 post free; Case and binding, £7·50 post free. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers, who will also undertake the binding if desired.

ADVERTISMENTS.—All communications should be addressed to *Hexagon Publishing Co. Ltd., 10 Spencer Street, St Albans, Herts AL3 5EG* (telephone St Albans 60641).

Instructions to Authors

PREPARATION OF MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

ILLUSTRATIONS AND TABLES

Illustrations should be clearly marked on their backs to show number, orientation and author's name. Explanatory legends should be typed on a separate sheet of paper accompanying the manuscript. For halftones, glossy photographs or positive prints (*not* X-ray negatives or slides) should be sent, unmounted wherever possible. When coloured illustrations are submitted as colour prints, they should be accompanied by the original transparencies where possible. As colour illustrations are expensive to reproduce, authors may be asked to make a contribution towards the cost. Drawings should be in a finished state suitable for reproduction. Any lettering should be large enough to withstand a reduction in size; sans serif lettering is recommended.

Tables should be typed on separate sheets of paper accompanying the manuscript. They should have an identifying number and a short descriptive heading. *All illustrations and tables must be referred to in the text.*

REFERENCES

The citation of references should follow the pattern shown in the Reference Citation Recommendations issued by the Medical Section of the Library Association. Copies of these recommendations can be obtained from the Secretary, Medical Section, The Library Association, 7 Ridgmount Street, London WC1E 7AE.

The name of the author and the date of publication are given in the text; the list of works cited is put at the end of the article, arranged in alphabetical order of authors' names. When references to two or more works by the same author are listed, they are arranged in chronological order. Where there are two or more authors (apart from the main author), these may be indicated in the text citation by the words 'et al.', following the name of the principal author; on the rare occasions when this may lead to confusion, the text citation should name as many of the collaborating authors as are necessary to identify the work cited. When several works published by the same author(s) in the same year are cited, they should be distinguished by the letters a, b, c, etc., placed immediately after the date.

In the list of works cited each reference to a *journal article* should give, in the order indicated, the names and initials of all authors, the year of publication (in parentheses), the title of the paper, the name of the journal (abbreviated), the volume number (in heavy type arabic numerals) and the numbers of the first and last pages of the article. Abbreviations for journal titles should be those adopted by *Index Medicus* since January 1971; where no abbreviation is given by *Index Medicus* the journal title should be left in full and the publishers will provide a suitable abbreviation. A reference to a *book* should give, in order, the names and initials of all authors, compilers or editors, the date of publication (in parentheses), the title of the book, the edition number (if other than first), the place of publication, the publisher's name and, where appropriate, the number(s) of the page(s) referred to. A reference to a *contribution to a book* should give, in order, the names and initials of all authors of the contribution, the date of publication (in parentheses) and the title

of the contribution; then, after the word 'In:', there should follow the name(s) and initial(s) of the author(s) etc. of the book, the title of the book, the edition number (if other than first), the place of publication, the publisher's name and the numbers of the first and last pages of the contribution.

Titles of papers and books should be given in the original language, with titles in Cyrillic and Greek alphabets transliterated

Only in papers in which many and frequent references have to be made should the items be numbered; the numbers may then be inserted in the text without interrupting it with a list of names and dates.

A SYNOPSIS OF SURGICAL ANATOMY

Edited by D. J. du PLESSIS,
CHM (RAND), FRCS (ENG)

Head of the Department of Surgery,
University of Witwatersrand, Johannesburg;
Chief Surgeon, Johannesburg General Hospital

A general revision has been undertaken to bring the whole book up-to-date and also to eliminate those sections which were not absolutely essential because it is important to prevent a book of this type from becoming too large.

In preparation

JOHN WRIGHT
42–44 Triangle West, Bristol BS8 1EX

SENIOR SURGICAL SPECIALISTS

Salary £5,316 + Tax Free Gratuity

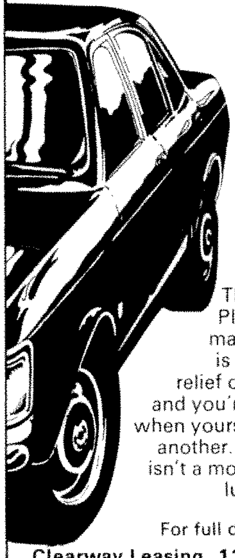
Senior Surgical specialists are required for central hospitals in Malawi. They will work as general surgeons and from time to time give specialist opinions to the Ministry of Health.

Candidates aged 25–55 should hold a qualification registerable in Malawi and post-graduate training in general surgery equivalent to fellowship of the Royal College of Surgeons.

Generous paid leave with free passages and baggage allowance. Education allowances and subsidised housing. Loan for the purchase of a car. Free medical attention.

Please apply to MALAWI BUYING AND TRADE AGENTS, Recruitment Section, c/o Berners Hotel, Berners Street, London W1A 3BE for application form and further details quoting reference number 806/B.

Malawi



NEW CAR?

NO CAPITAL OUTLAY

The Clearway Executive Leasing Plan offers you the choice of any make or model, what's more there is no capital outlay and 100% tax relief on your annual leasing charges, and you're never without a car, because when yours is being serviced we lend you another. For the professional man there isn't a more economical way of ensuring luxurious, trouble free motoring.

BLOOD COMPATIBLE SYNTHETIC POLYMERS: An Introduction *by* **Stephen D. Bruck,** *National Institutes of Health, Bethesda, Maryland.* Intended for investigators and students in biomedical curricula and polymer science. Organized in three chapters, the book first gives an outline of macromolecular science with biomedical application in mind. The second chapter discusses the biological environment with specific references to hematological and physiological considerations, neither of which may be familiar to many physical scientists. The third chapter stresses the important problem areas in the interaction of blood with synthetic materials. *'74, 144 pp., 69 il., 14 tables, $9.75*

SAFE CENTRAL VENOUS NUTRITION: Guidelines for Prevention and Management of Complications *by* **Mohamad H. Parsa, Jose M. Ferrer** *and* **David V. Habif,** *all of Columbia Univ., New York.* A comprehensive text prepared for the clinician and investigator engaged in intravenous feeding. A practical guide emphasizing technical and metabolic knowledge required to prevent the potential complications of this treatment. Complications that may occur during placement of central venous catheters and their long-term maintenance are discussed. Also considers methods of infusion, laboratory tests necessary for proper dosage, and metabolic complications such as hypoglycemic reaction. *'74, 280 pp., 132 il., 43 tables, $17.50*

REHABILITATION OF THE FACIALLY DISFIGURED: Prevention of Irreversible Psychic Trauma by Early Reconstruction *by* **J. J. Longacre,** *Univ. of Cincinnati, Cincinnati, Ohio. (2 Contributors)* Observations of the psycho-socio-economic effects of wounding over a period of more than thirty years are presented. This work points out the difference in the effect of early versus late definitive care and its long-range results, especially of the congenitally deformed before they have been exposed to repeated traumatic experiences when they leave the shelter of their homes. Stressed is the importance of the immediate definitive care of severe facial wounds with associate multiple fractures during the first six to eight hours following injury which produces gratifying restoration of individuals who otherwise would become permanently mutilated. *'73, 144 pp. (7 x 10), 384 il., 2 tables, $14.75*

BILIARY TRACT SURGERY AND CHOLANGIOGRAPHY *by* **Vernon L. Stevenson,** *Univ. of Utah Hospital, Salt Lake City.* This book was written to emphasize the importance of operative cholangiography to the surgeon unfamiliar with this technique. Operative cholangiography has led the way to other diagnostic techniques such as angiography and other methods of localizing abnormalities. The second most common operation, that of the biliary system, is extremely technical. Operative injuries to the biliary tract that can be avoided are discussed, and certain cardinal rules for the avoidance of these disasters are provided. *'73, 200 pp., 41 il., $11.50*

THE PORTAL VENOUS SYSTEM *by* **Charles Marks,** *Louisiana State Univ. School of Medicine, New Orleans. Introduction by* **Isidore Cohn, Jr.** Although a great deal of literature exists on various aspects of liver disease, portal hypertension and the anatomy of the portal venous system, this volume places in comprehensive perspective the interrelated information regarding the portal venous system. It effectively utilizes a combination of embryologic and anatomic data in relation to clinical aberrations of the normal and their relationship to clinical problems. *'73, 160 pp., 57 il., $12.75*

CARCINOIDS OF THE GASTROINTESTINAL TRACT *by* **Richard J. Sanders,** *Univ. of Colorado, Denver.* This book covers the history, histochemistry, biochemistry, pharmacology, physiology, clinical features and treatment of carcinoid tumors. The surgical management and prognosis of carcinoid tumors in each area of the gastrointestinal tract is discussed. All of the currently used forms of treatment are covered. *'73, 148 pp., 23 il., 14 tables, $13.75*

ACUPUNCTURE FOR PHYSICIANS *by* **Teruo Matsumoto,** *Hahnemann Medical College and Hospital, Philadelphia.* All acupuncture points are described in Japanese and Chinese. In addition, these names have been converted to familiar medical nomenclature for physicians. Liberal use of photographs, figures and tables facilitate in the understanding of this art. Special efforts were made to provide information in a very concise manner integrating acupuncture into modern medicine practiced throughout the world as another ancillary tool for the care of patients. *'74, 224 pp. (6 3/4 x 9 3/4), 175 il. (3 in full color), 6 tables, $14.75*

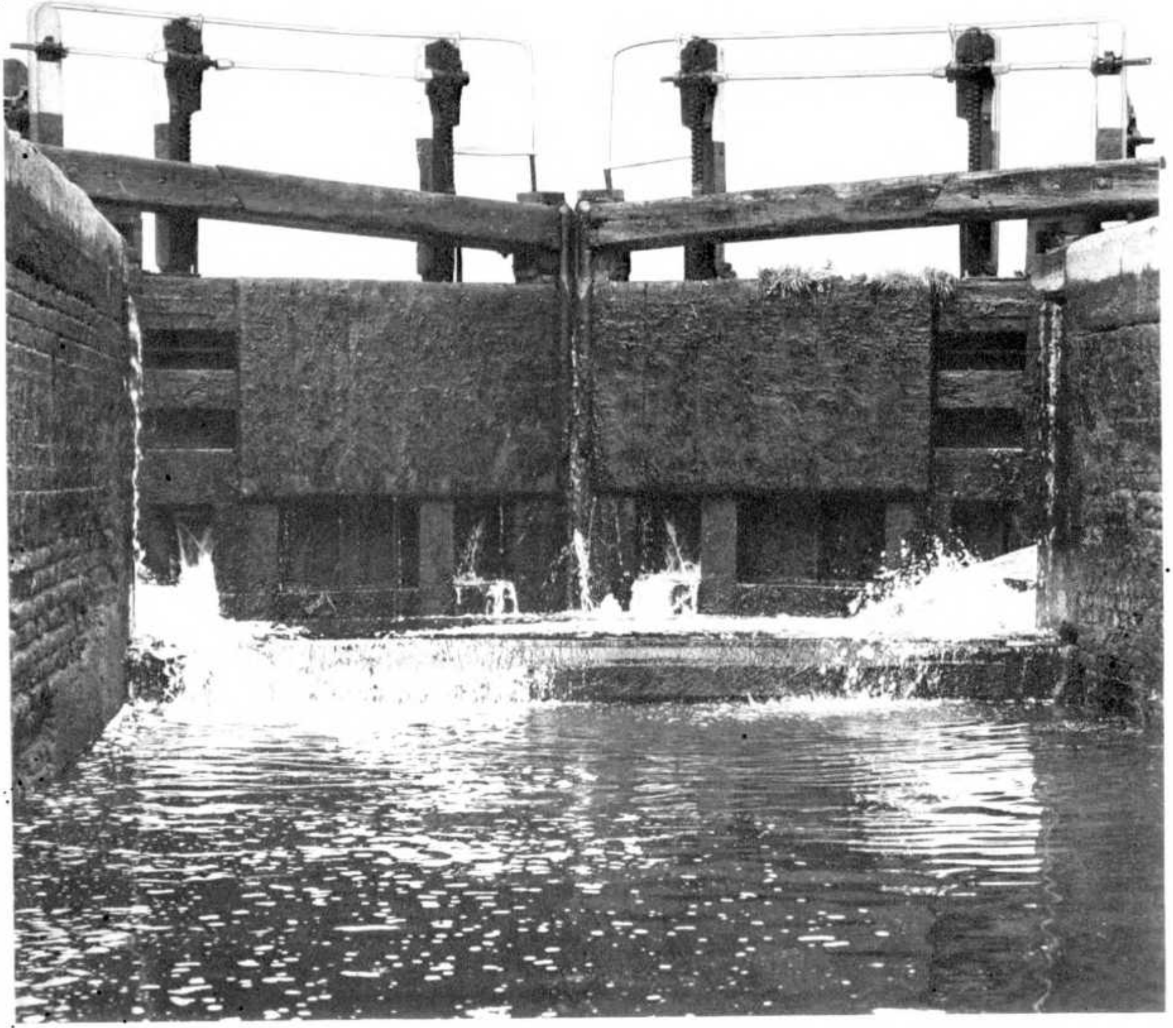
A new concept in the control of occlusive vascular disease

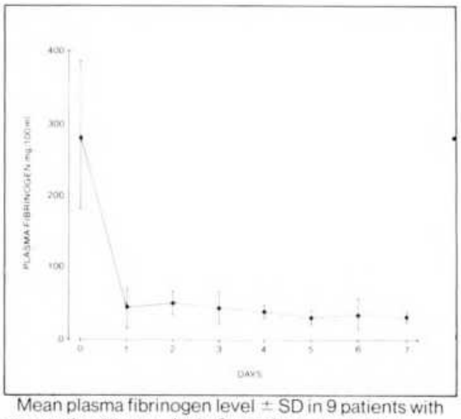


x

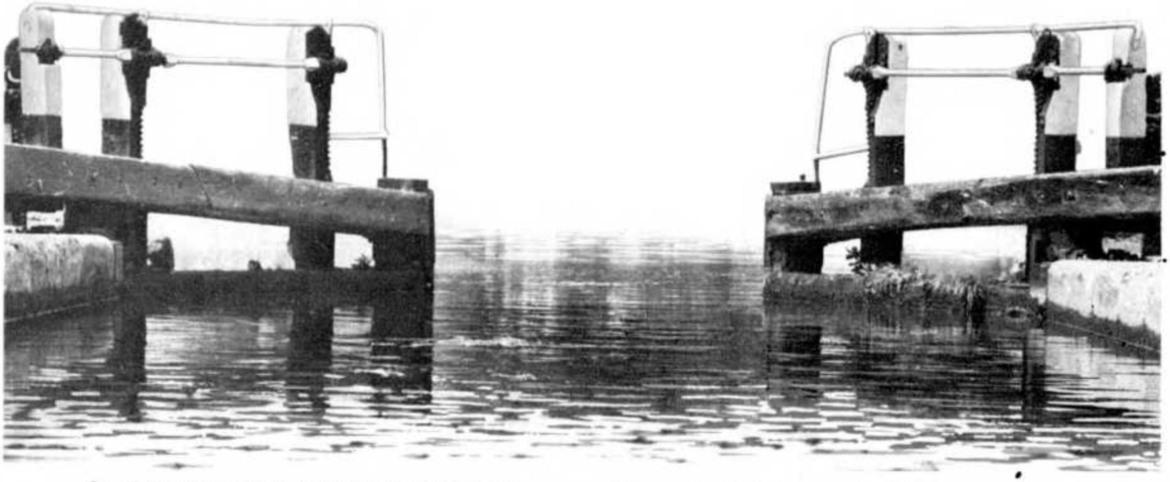
A unique drug is now available to the specialist for routine anticoagulant therapy, and to the researcher as an aid to the elucidation of thromboembolic disorders. Its name is Arvin.

Arvin reduces plasma fibrinogen to a level that maintains marked hypocoagulability without serious spontaneous bleeding complications. This desirable effect is achieved through the specificity of Arvin for fibrinogen—other clotting factors are unaffected.

This state of 'pure' defibrination has an important clinical place when prophylactic measures need to be taken in occlusive vascular disease. e.g. to prevent the formation and extension of thrombi and the dissemination of emboli.



Mean plasma fibrinogen level ± SD in 9 patients with venous thromboses. Arvin 2 units/kg body weight intravenously every 12 hours. From Pitney WR. (1971). Thromb. Diath Haemorrh, *45*, 43.



Consistent features of Arvin therapy include an absence of thromboembolic events during treatment, absence of fibrinogen rebound and low incidence of rethrombosis after treatment has ceased. On withdrawal, plasma fibrinogen returns to haemostatic levels within 12 hours and to normal after 10-20 days. Thus, the changeover to oral anticoagulants is smooth and complication-free.

A consistent dose-effect relationship which ensures simple and precise control methods has been established for Arvin. On this basis, we can recommend this drug for a range of indications where controlled therapeutic defibrination is desirable.

For instance, deep vein thromboses, central retinal and branch vein thrombosis, priapism, pulmonary hypertension of embolic origin, embolism after prosthetic cardiac surgery and rethrombosis after thrombolytic therapy have been shown in clinical trials to respond well to Arvin.

To find out more about the unique Arvin concept specialists are invited to write to us for detailed clinical literature and prescribing information.

Trans-sphenoidal hypophysectomy in disseminated carcinoma of the breast

P. E. ROBIN, D. JEAN POWELL, J. A. H. WATERHOUSE AND G. A. DALTON*

SUMMARY

One hundred and eight patients with advanced carcinoma of the breast were treated by trans-sphenoidal hypophysectomy and followed up for at least 1 year. The results were assessed both by clinical response and objectively by survival following hypophysectomy, as expressed by the survival ratio. The two methods showed close correlation.

The results show that there is a variation in response relating to menopausal status and age at diagnosis, subsequent hormonal manipulation and physical condition at hypophysectomy. Younger patients whose carcinoma is diagnosed after menopause carry a good prognosis, yet the older premenopausal patients, especially if their clinical condition is poor, do not benefit. Easily available clinical information can be a guide to prognosis.

OF a series of trans-sphenoidal hypophysectomies, 108 consecutive patients who have been followed up for at least 1 year have been analysed. These patients were referred by surgeons, radiotherapists and physicians from the area covered by the Birmingham Regional Cancer Registry. Their ages at hypophysectomy ranged from 33 to 73 years, but at the time of diagnosis they were between 30 and 69 years. All the patients had had some previous treatment before being referred for hypophysectomy. When referred there was clinical evidence of extension of disease beyond the regional nodes.

Of 112 patients who were referred, 2 were rejected because of chronic sinus sepsis and 2 because the pituitary fossa was grossly destroyed by tumour. There was no other selection, and no preoperative test was used to predict response. Thus all patients were accepted for palliative operation whatever their clinical condition. Details of the operation have been described previously (Kapur and Dalton, 1969).

The assessment of the effect of various treatments of carcinoma of the breast has always been difficult. There is controversy even about the results of mastectomy (Crile, 1968), the earliest and most obvious procedure. To assess the effect of hormonal manipulation is in many ways more difficult since by the time such a procedure is adopted a multiplicity of treatments may have already been applied; yet in some ways it is easier since each subject is nearer the termination of life, and it is possible to use death or its delay—that is survival—as a measure of response.

A further complication in assessment is provided by the biological variation in tumour behaviour in carcinoma of the breast. Few tumours are associated with such variation and unpredictability. Assessment of response to a therapeutic procedure must take this into account. Our method proposes a means by which this may be done.

Calculation of survival ratio

Hypophysectomy is generally recommended for cases of carcinoma of the breast where there is evidence of spread beyond the regional nodes. Another way to describe this state would be to say that had the condition been such at the initial diagnosis the case would have been called stage IV (Paterson et al., 1950). We have described the time of initial diagnosis as *P* (*Fig.* 1), and the appearance of the recurrence or metastasis as *M* (i.e. the relevant extension). It is well known that some cases present initially with clinical metastatic disease, while others do not do so for many years—20 or more on occasions. One would anticipate that the case presenting with an early metastasis (*P–M* is short) will have a relatively more aggressive cancer and a worse prognosis, while one without metastasis for many years (*P–M* is long) will be the reverse. This assumption, which is fundamental to our concept, is demonstrated in the figures of the Birmingham and any Cancer Registry.

The actual survival time of patients who had undergone hypophysectomy was assessed and related to the expected survival, taking into account the rapidity

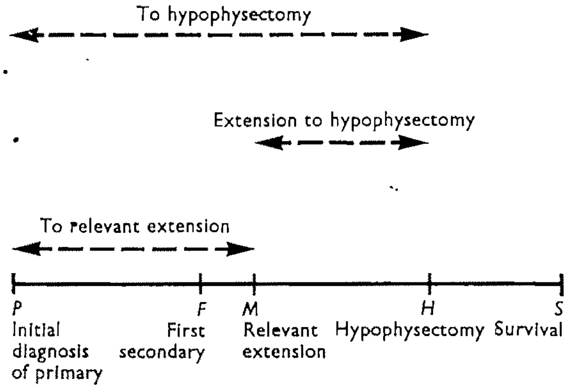

Fig. 1. Diagrammatic representation of the intervals used to calculate the survival ratio. Survival is calculated to the endpoint of survey or death. Any of the following points may coincide (with the consequence that the interval between is zero): *P* and *F*; *F* and *M*; *P, F* and *M*; *M* and *H*; *H* and *S*.

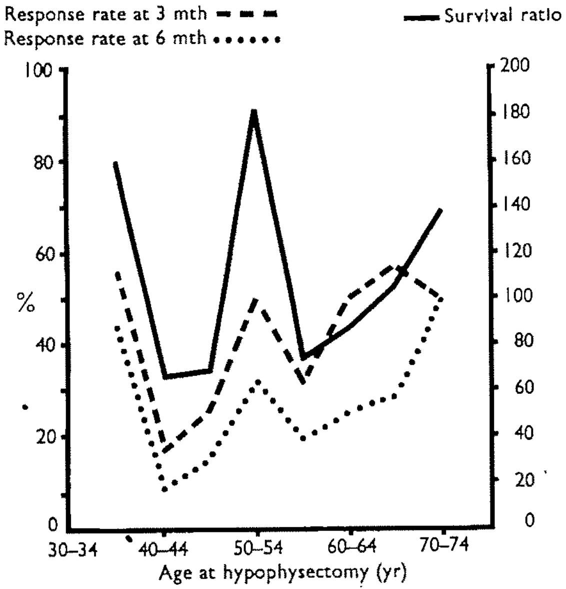

Fig. 2. Survival ratio and response rate compared with age at hypophysectomy.

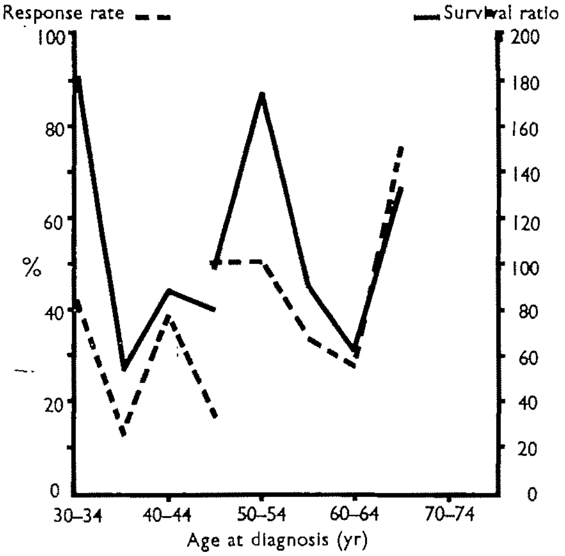

Fig. 3. Survival ratio and response rate compared with age and menopausal status at time of diagnosis.

of the progress of the disease. For example, an individual with a short *P–M* interval would, on average, have a short life expectancy. If hypophysectomy were to double the expected survival, we could confidently state that hypophysectomy had produced a response. Conversely should the *P–M* interval be long, life expectancy would be relatively high, and it would be necessary to extend an already relatively long expectancy still further to show a response. As will be seen, other observations of response correlate with this much more objective assessment, the *survival ratio.*

Controls

From the records of the Birmingham Regional Cancer Registry all the cases diagnosed as suffering from carcinoma of the breast during 1960–4 were collected. (The Registry covers the same area as that from which our hypophysectomy cases are referred.) Altogether 8329 cases were recorded. Because the hypophysectomy cases were within the age range 30–69 years, only those in this age range were used as controls. The number was thus reduced to 6202. Of these, only 2199 were recorded as having developed a relevant extension (*M*), the criterion which could make such a patient a candidate for hypophysectomy. Thus a control group of 2199 cases was obtained. The detailed life expectancies of the 1960–4 control patients were compared with those of a previously well-studied series of patients diagnosed during 1936–50; it was found that the prognosis of the disease had not substantially changed over this long period. The 2199 control cases were then grouped by age and by stage (*Tables I, II*) at initial diagnosis. The control series will be seen to match the larger regional group closely by age. (That the hypophysectomy group does not do so is probably due to the tendency for hypophysectomy referrals to include a higher proportion of younger candidates, a reflection of the preference of the referring practitioner.) However, the control series does differ markedly from both the regional and hypophysectomy groups in its stage distribution. The shift towards the later stages is a reflection of the fact that the controls were chosen to be patients who had either at the time of diagnosis or later developed a relevant extension (i.e. were of comparable severity to the hypophysectomy group). Thus all patients who presented as stage IV are included among the controls. The higher proportion of stage I cases in the hypophysectomy group is likely to be a reflection of their better physical condition which would influence their referral. Discrepancies, whether in age or stage, do not, however, invalidate the assessment since comparisons were made by selecting for each hypophysectomy case the appropriate stage and age groups from the control series.

This was done by forming subdivisions according to stage within each age group; thus for the age group 30–4, subgroups were made according to clinical (and pathological) stages, and likewise for all other age groups. For each subgroup a linear regression equation was developed to summarize in the form of a simple relationship the time between the development of the relevant extension (M) and time before death (S). Since in all cases the fate of our controls was known, our calculations were based on observed facts. Thus, given the age, date of diagnosis (P), clinical stage at diagnosis and the date of the relevant extension (M), we could predict, on the basis of a large number of controls, the expected survival of any individual. By dividing the actual time of survival of a hypophysectomized patient by the expected survival and expressing the answer as a percentage the *survival ratio* is obtained.

Assessment of results

Survival ratio

The effect of hypophysectomy on the survival ratio is demonstrated in *Fig.* 2 where it is related to age at the time of hypophysectomy. It is evident that the proportion obtaining benefit from the operation is variable. Probably the most important feature demonstrable is the parallel relationship between the survival ratio and the response rate. This reassuring finding confirms our previously unsubstantiated belief in the validity of our observations of response rate.

Response rate

This index, adopted by others (Pearson and Ray, 1960), uses an observation of reduction in size or extent of metastases, or subjective improvement in pain or disability. While criticized elsewhere because of lack of objectivity, its close relationship to the objective survival ratio is shown. In addition it is clear from *Fig.* 2 that the response at 3 months is paralleled, at a lower level, at 6 months. No doubt a further reduction would be observed at 12 months. Overall the 3-month rate was 39 per cent but at 6 months was 24 per cent.

Factors affecting prognosis

Both response rate and survival ratio show relationships with menopausal status and age at diagnosis, and with preoperative physical condition.

Age and menopausal status

That the menopause is a significant feature is shown in *Fig.* 3, the pre- and postmenopausal response rates at 3 months being 28 and 44 per cent respectively. Age is that at diagnosis, as is the menopausal status. (All the premenopausal cases in our series had had a natural or artificial menopause before referral for hypophysectomy.) Hypophysectomy is less favourable in patients whose carcinoma is diagnosed before menopause, and becomes even less favourable as the nearness to menopause increases. Conversely the best response rate (50 per cent) is in those who are postmenopausal but relatively younger at the time of diagnosis (*Table III*). This is likewise reflected in the survival ratio (*Table IV*).

Table I: DISTRIBUTION BY AGE AT INITIAL DIAGNOSIS (TRUNCATED AGE RANGE)

Age (yr)	Regional series (%)	Hypophysectomy series (%)	Control* series (%)
30–34	2·5	11·1	2·4
35–39	6·0	8·3	5·5
40–44	11·7	16·7	10·1
45–49	16·0	21·3	14·2
50–54	16·2	17·6	18·1
55–59	16·9	11·1	18·2
60–64	15·8	10·2	16·8
65–69	14·9	3·7	14·7
Total no. of cases	6202	108	2199
Mean age	53·8	48·4	54·3

Table II: DISTRIBUTION BY STAGE AT INITIAL DIAGNOSIS

Stage	Regional series (%)	Hypophysectomy series (%)	Control series (%)
I	44·4	41·5	26·6
II	24·5	25·5	22·4
III	17·2	18·9	23·4
IV	13·9	14·1	27·6
Total staged	4389	106	2199

Includes only cases aged 30–69 years at time of initial diagnosis but excludes those without clinical staging.

Physical condition preoperatively

This factor was graded into three levels: 'fit', 'moderate' and 'poor' (*Table V*) according to the criteria listed. *Table VI* shows the mean survival ratio for each group. In each category the poor group fared badly. Because 3 patients exceeded their life expectation by more than ten times, these were excluded owing to the possibility that their inclusion might distort the results; however, the results are not materially affected. It is of course significant that postoperative deaths occurred only in the moderate and poor groups and amount to 10 per cent, though only 2 per cent can be attributed to surgery.

Physical condition and menopausal status

The combination of these two factors provides the best index of prognosis that we have found. Patients who were premenopausal at diagnosis and whose physical condition was poor fared uniformly badly (0 per cent response) with hypophysectomy (*Table VII*), while the converse was true for the postmenopausal and fit (83 per cent).

Previous hormonal treatment

In 70 per cent of the subjects previous hormonal treatment, either administration of hormones or glandular ablation, had taken place so that some assessment of each subject's response to hormonal

Table III: RESPONSE RATE AT 3 MONTHS COMPARED WITH AGE AND MENOPAUSAL STATUS AT TIME OF INITIAL DIAGNOSIS

	All cases		Premenopausal		Postmenopausal		At menopause or NK	
Age (yr)	No.	%	No.	%	No.	%	No.	%
30–34	12	41·7	12	41·7	—	—	—	—
35–39	8	*12·5*	8	*12·5*	—	—	—	—

65–69	4	*75·0*	—	—	4	*75·0*	—	—
All ages	103	38·8	46	28·3	50	44·0	7	71·4

In 5 cases the response was not known. Rates based on less than 10 cases are in italic figures.

Table IV: MEAN SURVIVAL RATIO COMPARED WITH AGE AND MENOPAUSAL STATUS AT TIME OF INITIAL DIAGNOSIS

	All cases		Premenopausal		Postmenopausal		At menopause or NK	
Age (yr)	No.	%	No.	%	No.	%	No.	%
30–34	10	181·6	10	181·6	—	—	—	—
35–39	9	52·5	9	52·5	—	—	—	—
40–44	17	111·4	14	88·0	1	163·5	2	248·9
45–49	23	88·1	13	79·1	8	97·2	2	110·7
50–54	18	155·6	1	0·0	15	174·5	2	92·1
55–59	10	90·4	—	—	10	90·4	—	—
60–64	9	62·5	—	—	9	62·5	—	—
65–69	4	133·5	—	—	4	133·5	—	—
All ages	100	110·6	47	97·0	47	118·3	6	150·6

Excludes 3 'outliers' (cases where the survival was more than ten times that expected), and 5 cases (not the same as those omitted from *Table III*) omitted for lack of data.

Table V: ASSESSMENT OF PREOPERATIVE PHYSICAL CONDITION

Poor:	Confined to bed with severe pain Dyspnoea at rest Bilateral pleural effusions Ascites Paraplegia
Moderate:	Impaired mobility with widespread metastases Pleural effusion requiring preoperative aspiration Anaemia requiring preoperative transfusion Renal impairment
Fit:	Relatively minor disabilities Permitted more or less normal daily life

Table VI: SURVIVAL RATIO COMPARED WITH PHYSICAL CONDITION

	Fit		Moderate		Poor	
	No.	%	No.	%	No.	%
All cases	26	223·9	48	198·9	29	47·4
Excluding 'outliers'	25	157·8	46	123·9	29	47·4
Excluding operative deaths	26	223·9	41	232·2	23	59·8
Excluding operative deaths and 'outliers'	25	157·8	39	145·5	23	59·8
Cases omitted for lack of data	2		1		2	

'Outliers': cases where the observed survival was more than ten times that expected.
Omissions are: 2 cases not staged; 2 in which the interval was indeterminate; 1 case who was still alive but for whom the survival ratio <100.

Table VII: RESPONSE RATE COMPARED WITH PHYSICAL CONDITION AND MENOPAUSAL STATUS

	Condition at hypophysectomy					
	Fit		Moderate		Poor	
Status at initial diagnosis	No.	%	No.	%	No.	%
Premenopausal	12	50·0	22	31·8	12	0·0
Postmenopausal	12	83·3	21	38·1	17	23·5

treatment was possible. No clear correlation between previous response and the response to hypophysectomy emerged (*Fig.* 4). Indeed, the survival ratio of 28 patients who had not shown a response was better than that of 46 who had previously responded to hormonal treatment. The types of hormonal treatment which had been received were so various that their evaluation was unreliable, but nevertheless two observations can be made. First, previous oophorectomy with adrenalectomy make a good response to hypophysectomy unlikely; secondly, a previous radiation menopause followed by hormonal treatment and then hypophysectomy has not been followed in our experience (13 patients) by any favourable response.

Quality of life after hypophysectomy

When an operation is palliative the subjective attitude is of prime importance. We have made an assessment of the quality of life before and after hypophysectomy. The patients were grouped into three broad categories:

'normal', able to carry out normal day to day activities or employment; 'restricted', where employment, shopping, etc., was limited; 'poor', where the patient was more or less housebound, unable to walk without an attendant or manage her own home or was bedridden. The assessment was made without reference to response.

Table VIII compares these groups. In general, improvement in the quality of life and our assessment of response went hand in hand. Whether the deterioration associated with non-response was a result of operation is unclear.

Discussion

Though others have demonstrated that hormonal manipulation in general and hypophysectomy in particular can produce a good response in patients suffering from carcinoma of the breast (Pearson and Ray, 1960) there have been difficulties in assessment.

These difficulties have been overcome by the use of a survival ratio, because it is both objective (since it relies on an objective measurement—death) and calculated on a follow-up period which is indefinite and independent of a specific time. The close comparability between results using the survival ratio and response rates should also counter suspicion of the latter.

The age of the subject has been quoted as relevant (Harrold et al., 1968), it being generally accepted that younger sufferers are most likely to have hormone-dependent tumours. We do not differ from this view, but would stress that the relationship is not direct, and is complicated by the menopause. That the menopause is involved is evident from the results of assessing together age and menopausal status at the time of diagnosis; so much so that we can only emphasize the observation of Harrold et al. (1968) that subjects who are approaching menopause (especially those with a late menopause) are relatively poor candidates for hypophysectomy. Our findings agree generally with others (Boeson et al., 1961; Edelstyn et al., 1968).

Other writers have used the results of previous hormonal treatment to predict a good or bad response to hypophysectomy (Boeson et al., 1961; Edelstyn et al., 1968). Our own series does not support them, for there are inconsistencies. If we were to draw any conclusion, it would be that previous hormonal manipulation had already 'used up' the response, but because of the variation and variety of therapies, we feel that no firm conclusion is justifiable.

The use of tests predicting response has not been practised by us. Of the many predictive factors and tests (Fairgrieve, 1965), we are impressed by only two. The measurement of urinary 17-hydroxycorticosteroids and aetiocholanolone (Bulbrook et al., 1960) is reasonable but lacks real accuracy, while the stimulation of hypercalcaemia using stilboestrol, attributable to Emerson and Jessiman (1956), applies only to patients with skeletal deposits, and may be followed by dangerous hypercalcaemia. The role of prolactin in prognosis has not yet been evaluated (Stoll, 1974).

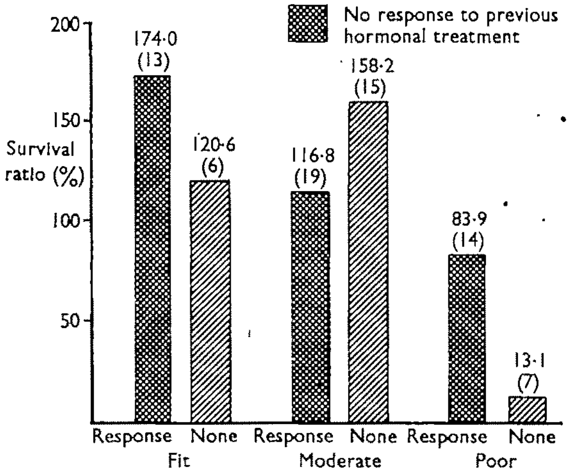

Fig. 4. Survival ratio following hypophysectomy compared with previous response to hormone treatment and physical condition at time of hypophysectomy.

Table VIII: COMPARISON OF RESPONDERS AND NON-RESPONDERS (EXCLUDING OPERATIVE DEATHS)

	Response	No response
Quality of life following hypophysectomy:		
Normal	46·1	4·2
Restricted	51·3	59·6
Poor	2·6	36·2
Compared with before hypophysectomy:		
Improved	89·7	10·6
No difference	7·7	55·3
Deterioration	2·6	34·1
No. of cases assessed	39	47

In 9 patients either the quality of life or response was not known.

The site of secondary deposits has been said to be important; skeletal deposits are said to respond better than most other sites. That this is widely believed is reflected in our finding that a little more than half our cases were referred because of skeletal deposits, while the expected proportion overall would be a quarter (Cole, 1965)—a fact which we can confirm from the Birmingham Cancer Registry figures. We have not sufficient experience of all the possible varieties of sites to make any firm conclusion, but it is our impression that multiple sites are reflected by a very poor physical state, which carries a proportionately bad prognosis.

We agree with Pearson and Ray (1960) that advanced disease leading to a moribund physical state is not likely to be associated with a useful response; also, from our other analyses it is this type of case which suffers the highest mortality in the postoperative period. Since it seems that such cases may suffer a deterioration in the quality of life, we feel that operation should be undertaken with reserve. Nevertheless, since we are content that improvement in life follows any degree of success, we are ready to recommend hypophysectomy as a palliative procedure in patients, especially younger ones, both pre- and post-menopausal, whose physical condition is less than critical, and to view with more reserve those in poor condition, particularly if they were initially diagnosed just before their menopause. Simple easily available clinical data therefore can help to predict many of the poor responders.

Statistical appendix

In this field it is difficult to formulate a method of assessment of the results of treatment which can be generally acceptable. There is an essential subjective element, mainly in terms of the patient's reaction and attitude, but inherent also in the clinician's appraisal, and the comparison of results from different centres is in consequence inevitably complicated by it. We have made use of the *response rate*, which is frequently employed in this field in order to facilitate comparability of results, but we have also developed a quantitative measure, the *survival ratio*, which expresses the actual duration of life with hypophysectomy in relation to that computed from a large control series.

The control group of patients was selected from the totality of cases of breast carcinoma seen in the Birmingham region in the years 1960–4. First, all the patients of the hypophysectomy group were excluded. From the remainder, only patients who had developed a 'relevant extension', in conformity with the definition given in the main text, were chosen, amounting to 2199 patients. The control group was divided into subgroups by clinical stage, pathological grade and 5-year age group. For each subgroup a linear regression equation was calculated between survival (from the time of development of the relevant extension) as the dependent variate, and the interval of time from initial diagnosis to development of the relevant extension as the independent variate.

This method was used because in practice it had proved often difficult, and sometimes not possible, to select an appropriate control case, one for one, on the basis of matching for the three characteristics stated. Two or more potential controls might be equally well suited—or indeed equally badly suited—to an individual hypophysectomy case, leaving an element of choice which was difficult to resolve without the introduction of bias. Moreover, it was not an infrequent finding that the space of time between the development of the relevant extension and the date of hypophysectomy exceeded the duration of life of the control case. To obviate these complications it seemed better to use a statistical method which took account of all the information available from the group of controls of a given age group, stage and grade by summarizing it in the form of a simple relationship (linear regression equation) between the time taken to develop the relevant extension and the subsequent survival.

It was thus possible to obtain for each hypophysectomy case an expected survival based on the behaviour of the appropriate control subgroup, paralleled for stage, grade and age group. However, without further adjustment the two groups would not be fully comparable, because of the interval in the hypophysectomy group from the relevant extension to the time of operation. It would be necessary in order to obtain full comparability to exclude the patients of the control subgroup who had died within this interval, which the hypophysectomy patient had of course survived. The adjustment was made by taking the distribution about the regression line, the mean value of which is the survival calculated from the regression equation, and the standard deviation of which is the 'standard error of estimate', and truncating it. The time to hypophysectomy from relevant extension, measured in units of the standard error of estimate, was used to obtain the point of truncation which would exclude from the calculation the controls whose survival was less than this time interval. The required figure for the expected survival, suitably adjusted for time to hypophysectomy, was then calculated for the section of the distribution remaining after truncation. Having made allowance for the actual survival of the hypophysectomy patient to the time of the operation, the calculated survival was now *an estimate of her further survival after the operation.* By dividing the actual by the expected post-hypophysectomy survival in each case and expressing the result as a percentage, the 'survival ratio' was obtained. When the survival ratio is greater than 100, then that hypophysectomized patient has survived longer than her expectation computed from the control series. The use of the survival ratio combines the advantage of an immediate evaluation of each case in terms of its own computed survival with the knowledge that the maximum of information in the control series has been entered into the computation. The individual ratios can be then treated as numerical assessments of survival when investigating the relevance of any other factors. Calculations of the denominator of the ratio—the expectation—can of course be used to provide an index of prognosis in a case referred for hypophysectomy.

> The senior professions of the Church and Law have always had prestige enough to enable each of them to keep a finger firmly and consistently in the governmental pie. They have therefore been able to see to it that any duty that was laid upon them should be set off by a corresponding privilege or immunity. The lowly and junior profession of Medicine, unlike its proud and elder sisters, has had no direct part and no direct influence in the work of government. It has therefore had to submit to its duties being piled up as occasion arose, with no resource for securing a due compensation of privilege and immunity except such slender sense of natural justice as governments possess, and their occasional doubts about the prudence of overloading a willing beast. These resources have shown all the ineffectiveness we might have expected. The result is that at a time when it is no longer possible to conceal the wholly unique importance of medicine for the very existence of social life, that profession finds itself of all professions the least in command of social prestige, the least privileged, the most exposed and the hardest worked.

Raised intracranial pressure due to spinal tumours: 3 rare cases with a probable common mechanism

R. S. MAURICE-WILLIAMS AND J. J. LUCEY*

SUMMARY

Three cases are reported of raised intracranial pressure associated with spinal tumours. The theories which have been advanced to explain this complication are discussed and it is suggested that in many of the reported cases the underlying mechanism may have been intracranial spread of the tumour and not a blockage of the cerebrospinal fluid pathways with proteinaceous deposits, as has been widely maintained. Autopsy revealed the former process to have operated in 2 of the 3 cases and it may have done so in the third. Two cases had unusual features in common: they were malignant schwannomas (a very rare spinal tumour) and they had both developed within the field of irradiation given for benign conditions many years previously.

RAISED intracranial pressure is a rare complication of spinal tumours situated below the cervicocranial junction, fewer than 30 cases having been reported in the English literature. In most of these cases the exact mechanism has remained uncertain, but it has been widely held that it is related to a raised protein concentration in the cerebrospinal fluid. Three further cases are reported here, and in 2 of them autopsy revealed that metastases had caused hydrocephalus by blocking the cerebrospinal fluid pathways. This may well also have been the explanation in the third case, where an autopsy was not performed.

Case reports

Case 1: A 69-year-old woman was admitted to hospital with pain in the right leg for 18 months, pain in the left leg for 3 months and progressive leg weakness and difficulty in passing urine for 3 weeks. Nineteen years previously she had been given radiotherapy to the lower abdomen after an ovarian cystadenoma had ruptured and seeded into the peritoneal cavity.

On examination she had retention of urine, a flaccid global weakness of both legs and hypalgesia from L5 downwards on the right and S3 downwards on the left. Myelography revealed an irregular intradural block opposite the L3 vertebral body. Cerebrospinal fluid from above the block contained a protein level of 680 mg/100 ml and 17 white cells (15 lymphocytes)/ mm.^{3}

At operation the roots of the cauda equina below the level of L2 appeared thickened and matted together, obliterating the subarachnoid space. The lumbar canal was extremely narrow and a generous laminectomy was performed, leaving the theca open, so that the nerve roots were released from considerable tension. A biopsy of the tissue binding the roots together was reported as showing arachnoidal proliferation but no tumour cells.

Postoperatively there was considerable neurological improvement and it was thought that the patient had a post-irradiation arachnoiditis aggravated by having the chronically inflamed cauda equina confined within a narrow lumbar canal.

Six weeks later her leg weakness worsened again and she became drowsy, confused and complained of headaches. She was readmitted to the neurosurgical unit and found to have bilateral papilloedema, a dense flaccid paraplegia and total sensory loss below the T10 level. Ventriculography revealed a communicating hydrocephalus due to obstruction of the subarachnoid cisterns at tentorial level. The ventricular CSF had a protein concentration of 252 mg/100 ml. It was surmised that the very high CSF protein concentrations had blocked the subarachnoid cisterns.

Insertion of a ventriculo-atrial shunt relieved the symptoms of raised intracranial pressure, but her neurological level gradually rose and she died 6 weeks later when it reached the upper cervical segments. At no time did any cranial nerve or root palsies appear above the main neurological level.

At necropsy the lumbar canal was found to be filled by an irregular tumour of 12 × 5 × 3 cm which was continuous with tumour tissue ensheathing the entire spinal cord and filling the basal cerebral subarachnoid cisterns (*Figs.* 1, 2). A thin layer of tumour thickened the leptomeninges over the brain surface but did not infiltrate the brain parenchyma. The Holter valve system was patent and the ventricles no longer dilated. The other organs of the body were normal and no stigmata of Von Recklinghausen's neurofibromatosis were found.

Microscopy revealed the tumour to be a malignant schwannoma with both compact and loosely textured areas. In the former areas the cells formed parallel rows and interlacing bands with some poorly developed nuclear palisading (*Fig.* 3). Mitotic figures and small areas of necrosis were frequent.

Case 2: A 56-year-old man developed leg weakness and retention of urine following haemorrhoidectomy and was admitted to the neurosurgical unit with a suspected central lumbar disc protrusion. Twenty-seven years previously he had undergone an operation for a lumbar disc protrusion and 21 years before he had been diagnosed as having ankylosing spondylitis and had been given radiotherapy to the thoracolumbar spine to a total dosage of 4800 rad.

On examination he was found to have double incontinence, hypalgesia from L5 down on the right and S3 down on the left, bilateral weakness of dorsi and plantar flexion at the ankle and absent ankle jerks. He had no stigmata of neurofibromatosis. Myelography showed a smooth intradural block opposite the body of L4. The cerebrospinal fluid from above the block contained no cells but had a protein level of 140 mg/100 ml.

At operation the lower roots of the cauda equina were found to be matted together with firm avascular tumour which was partially removed. Microscopy showed a malignant schwannoma composed of elongated spindle-shaped cells in interweaving bundles and large whorls, in areas of variable cellularity (*Fig.* 4). Small necrotic foci marginated by tumour cells were present and mitotic figures were numerous.

Despite a further course of radiotherapy the patient's neurological level began to ascend 2 months later. When it reached the midthoracic level he became confused and lethargic. He was found to have gross bilateral papilloedema, but no root or cranial nerve palsies above the main neurological level. He rapidly became comatose and died. A necropsy was not performed.

Case 3: A 44-year-old man presented in 1968 with remitting pain in the right buttock for 8 years and numbness in the right thigh and progressive weakness of both legs for 18 months. Myelography showed an obstruction at the T12 level and at operation an astrocytoma of the lower thoracic cord was diagnosed. Radiotherapy produced a transient symptomatic improvement, but when this paraparesis worsened a repeat

myelogram in May 1971 showed that the cord swelling had now reached the cervicothoracic junction. Further radiotherapy produced a partial remission and another myelogram in November 1972 showed that the cord expansion had receded to the midthoracic level, at which time his upper level of neurological dysfunction was T3. In mid-1973 he developed personality changes characterized by irritability, drowsiness, apathy and confusion. At the time these were attributed to toxaemia due to trochanteric and sacral pressure sores. He gradually declined and died in September 1973. Other than the mental changes, no neurological abnormalities were apparent at the time of his death above the T1 level.

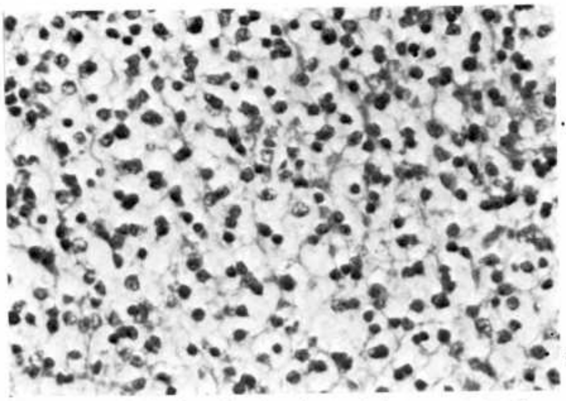

Fig. 5. *Case* 3. Section showing the typical appearance of an oligodendroglioma. HE. (×90.)

Necropsy showed the thoracic cord to be expanded by an intrinsic tumour with a soft haemorrhagic core. The entire fourth ventricle was blocked by tumour, which appeared to have spread up the central canal of the spinal cord in direct continuity with the main tumour mass, otherwise leaving the cervical cord unaffected. The blockage of the fourth ventricle had produced a gross dilatation of the ventricular system.

Histologically the tumour was an oligodendroglioma (*Fig.* 5). The tumour cells were loosely arranged in a delicate fibrovascular stroma. Mitotic figures were infrequent and the nuclei uniform.

Discussion

Spinal tumours situated distantly from the cranial cavity may on rare occasions give rise to raised intracranial pressure and papilloedema. Arseni and Maretsis (1967) reviewed 23 cases from the literature and reported 3 further cases of their own seen amongst 289 spinal tumours over a period of 30 years. Sometimes the symptoms and signs of intracranial hypertension may overshadow or precede those of the primary spinal lesion, so that the latter is overlooked in the search for a cerebral tumour (Neil-Dwyer, 1973).

Various mechanisms have been proposed by which this rise of intracranial pressure might be brought about. As in *Case* 1, metastases carried via the subarachnoid space may block the basal cisterns, causing a communicating hydrocephalus. Such a subarachnoid spread to distant regions by a spinal tumour is believed to be extremely rare. Three cases in which this occurred, a rhabdomyosarcoma and two malignant gliomas, were reported by O'Connell (1946), but in one of these cases the evidence for a subarachnoid spread was tenuous. In *Case* 3 described here, spread up the spinal cord central canal into the fourth ventricle occurred while the main bulk of the tumour was confined to the midthoracic region. A comparable case does not appear to have been reported previously.

In the majority of the cases reported, definite evidence of the underlying pathological process has been lacking and the exact mechanism has been a subject for conjecture. It has been widely held that the same process operates to produce papilloedema in spinal tumours as in the Guillain-Barré syndrome and poliomyelitis (Glasauer, 1964). It is suggested that the high CSF protein blocks the CSF circulation by coming out of solution, either in the basal cisterns (Harris, 1962) or in the arachnoid villi (Denny-Brown, 1952). However, the cause of the raised intracranial pressure in poliomyelitis and the Guillain-Barré syndrome is more likely to be generalized cerebral oedema, as in these conditions air studies have shown that the ventricles are of normal size, and not dilated as in the case of the spinal tumours with papilloedema (Weiman et al., 1951; Joynt, 1958). Joynt (1958) recorded a case of polyneuritis where exploration of one temporal lobe revealed diffuse cerebral swelling with intracellular oedema on microscopy.

In the case of spinal tumours the relationship between the CSF protein level and the presence of raised intracranial pressure is far from clear-cut. The CSF protein is commonly raised above spinal tumours, yet papilloedema is extremely rare. On the other hand, in many of the cases where papilloedema has been reported the protein levels have been raised only moderately, if at all (Love et al., 1951; Mittal et al., 1970). Arseni and Maretsis (1967) found that of 19 cases in the literature where the protein level was recorded, it only exceeded 200 mg/100 ml in 11 and 1000 mg/100 ml in 6. Gibberd et al. (1972) have suggested that a specific protein fraction may be involved, pointing out that in a case which they report the CSF immunoglobulin level was unusually high. These authors also point out that ependymomas —the type of spinal tumour most often reported as producing papilloedema—are particularly liable to subarachnoid bleeding, and that the combination of blood in the CSF and a raised CSF protein may be especially effective in exciting the formation of intracranial meningeal adhesions. Cases have been reported where at operation or necropsy a fibrous arachnoiditis has been found in the posterior fossa (Glasauer, 1964; Arseni and Maretsis, 1967).

In other cases it seems possible that the blockage is at the level of the arachnoid villi. No convincing evidence exists for this having occurred in the case of a spinal tumour, but Denny-Brown (1952) reported a case of polyneuritis where autopsy showed the pacchionian bodies to be blocked with a protein sediment beginning to recanalize. Such a process would fit the fact that in some instances removal of the spinal tumour has been accompanied by regression of the papilloedema (Love et al., 1951). This seems less likely to occur once arachnoid fibrous adhesions have formed, for cases of communicating hydrocephalus due to basal cistern blockage from other causes (meningitis, previous subarachnoid haemorrhage) do not generally resolve spontaneously. Silting up of the arachnoid villi with protein is consistent with the observations of Gardner et al. (1954) that in dogs the addition of autologous serum to the CSF reduces the rate of CSF absorption, although the CSF protein returns rapidly to normal once the protein infusion is discontinued. Recently, however, it has been shown that the CSF–blood junction in the arachnoid villi consists not of a semipermeable membrane against which protein could silt, but of valvular pore connections 7–8 μ in diameter—that is, large enough to permit the passage of red cells, let alone large protein molecules (Welch and Friedman, 1960).

Other postulated mechanisms contributing to the rise of intracranial pressure seem less likely. The suggestion that a complete spinal block will reduce CSF absorption by cutting off absorption via the lumbar sac roots is implausible as so little of the CSF is normally absorbed by this route (Teng et al., 1960). A slowing of CSF absorption by increased CSF osmotic pressure seems ruled out as a protein increase of 300 mg/100 ml will only increase CSF osmotic pressure by 9 mm of water (Gardner et al., 1954). Davson et al. (1970) suggested that CSF flow was reduced owing to the increased protein increasing its viscosity and showed that the rate of absorption was reduced by infusing Dextran, which increases its viscosity.

In few of the reported cases has the responsible mechanism been clearly demonstrated at necropsy. Harris (1962) and Arseni and Maretsis (1967) reported necropsy findings of adhesive intracranial arachnoiditis, and Teng et al. (1960) mentioned that in one case the necropsy revealed metastatic tumour in the basal cisterns. In all case reports a raised CSF protein has been put forward as the major aetiological factor. In this respect the details of *Case* 1 here are instructive. A very high protein level, both above the block and in the ventricles, was found and it was assumed that a protein precipitate was causing the hydrocephalus. The macroscopic appearance of the basal cistern adhesions at necropsy seemed to confirm this, and only microscopic examination revealed the presence of tumour cells. It may well be in fact that in many, perhaps most, of the reported cases such a neoplastic arachnoiditis was present. Two-thirds of the cases reported have been of ependymomas (Arseni and Maretsis, 1967), a type of tumour known to be particularly liable to subarachnoid spread when it occurs intracranially. In some cases biopsies of posterior fossa adhesions have been reported as showing fibrous tissue only (Love et al., 1951), but, as in *Case* 1, a fragment of a neoplastic adhesion may not with certainty allow the identification of tumour cells, and surgically the removal of other than a small piece of a dense adhesion without damaging adjacent structures can be extremely difficult. *Case* 2, where an autopsy was not obtained, might have shown the same mechanism at work as in *Case* 1. However, although metastatic obstruction of the basal cisterns may account for the occurrence of raised intracranial pressure in many of the reported cases, there remains a residue of cases with a benign tumour where this cannot be the explanation, as in 4 of 26 cases reviewed by Arseni and Maretsis (1967), or as in the extradural meningioma with a CSF protein of less than 100 mg/100 ml reported by Mittal et al. (1970).

Cases 1 and 2 have two further and extremely unusual features in common. Both were histologically malignant schwannomas, a type of tumour which has recently been stated to be virtually unknown within the spinal canal (Northfield, 1973), and in both cases the fields of origin of these unusual tumours had been subjected to radiotherapy for an unrelated condition many years before. The relationship of this radiotherapy to the development of these tumours can only be surmised, but earlier reports of central nervous system tumours apparently arising within previously irradiated areas have been extremely few and the tumours concerned have all been of mesodermal rather than of neurectodermal origin (Russell and Rubinstein, 1971).

Acknowledgements

We should like to thank Mr R. C. Connolly and Mr J. C. M. Currie for permission to report cases treated under their care. We are also grateful to Mr P. Crocker for the photomicrography.

Arteriographic exposition of the parathyroids

F. EFSEN, E. BRUUN, K. LOCKWOOD AND E. HASNER*

SUMMARY

Arteriographic exposition of the parathyroids in 52 patients consecutively referred for primary hyperparathyroidism is reported. Thirty-nine patients underwent neck exploration. In 29 patients pathologic parathyroids were found. The arteriographic evaluation was based on observation of the course of the inferior thyroid artery and the presence of parenchymal opacification. Comparison of arteriography and surgical findings revealed that selective angiography of the inferior thyroid artery had a high sensitivity and specificity in the detection of pathologic parathyroids far exceeding that of a non-selective technique.

IDENTIFICATION of all the parathyroid glands was established as a principle for surgical exploration over 40 years ago (Churchill and Cope, 1934). The complexity of the clinical findings and the biochemical disturbances present in primary hyperparathyroidism (PHPT) make preoperative visualization desirable. At present angiography appears to be the only method offering a possibility of estimating the volume of even normal parathyroids. Using angiography the course of the inferior thyroid artery can be visualized as proposed by Radner (1949) and described by Seldinger in 1953 and 1954. Parenchymal opacification of parathyroid tissue was described by Doppman et al. (1969). Both criteria have been applied in the present study.

Materials and methods

The present prospective study is based on a consecutive series of 52 patients referred for PHPT; there were 30 men and 22 women with mean ages of 46·1 years (range, 19–76) and 53·6 years (range, 26–78) respectively.

Thirteen of the 52 patients were not operated on because of lack of evidence for the diagnosis. Neck surgery was performed in 39 cases. Decisions to undertake neck exploration were based on anamnestic, clinical, radiological and biochemical data. A diagnosis of PHPT was confirmed at surgery in only 29 of the 39 patients (*Table I*). The ultimate diagnosis of PHPT was based on microscopical examination of the parathyroid glands (Werdelin, 1964).

Retrospectively we have attempted to weight the probability/evidence of correctness of our tentative diagnosis on the basis of the pre-admission history, objective findings, results of conventional radiology and biochemical findings. This classification resulted in the following four groups of different clinical evidence of PHPT: 'evident', 'plausible', 'not to be excluded' and 'unlikely' (*Table I*). The level of serum calcium† showed significant differences between the four groups in spite of wide ranges ($P<0·001$, Mann–Whitney *U*-test). One patient only was classified as 'unlikely'.

Angiography

Bilateral examinations were performed in 46 patients and in 6 patients unilateral examinations were performed, totalling 98 investigations. Twenty-eight angiographs of the inferior thyroid artery were carried out and are referred to as 'selective'. Care was taken that the blood flow around the catheter tip was unimpaired. The remaining 70 angiographs were performed with a lesser degree of selectivity and are referred to as 'non-selective' examinations.

Bilateral and unilateral examinations and selective and non-selective angiographs were equally distributed without significant differences between the 'evident', 'plausible' and 'not to be excluded' groups ($P>0·2$, Fisher's exact probability test).

Torsion stable catheters (Ducor, Cordis Inc., or Torcon, Cook Inc.) were inserted transfemorally during local anaesthesia using the Seldinger method. In all the patients the first catheter inserted was a 'right coronary (5 cm)' which could always be advanced into the left subclavian artery. In cases where this catheter could not be moved from the aorta into the anonymous or right subclavian artery it was replaced by a so-called 'head hunter' catheter. Later in the series the technique was modified into percutaneous catheterization of the right brachial artery using a 'femoral-visceral I' catheter.

The contrast medium used was Urografin meglumine (diatrizoate meglumine, BP) containing 306 mg of iodine/ml. In selective arteriography of the inferior thyroid artery the dose was 5–6 ml injected at a rate of 4–5 ml/sec. The dose in non-selective examinations was 18–20 ml delivered at a rate of 10–12 ml/sec. Radiographs were made in three series, starting at a rate of four per second for 3 seconds, followed by one per second for 4 seconds, and one exposure every third second for the last 12 seconds.

Angiographic evaluation: This was based on findings in the thyroid gland and adjacent structures, especially the mediastinum, as described below:

1. The presence of arteries having a stretched curvolinear course, indicating the probability of a *space-occupying process*.
2. *Parenchymal opacification* within the area circumscribed by the above arteries or placed elsewhere in the neck.

Hypercalcaemic	7 (7)	17 (16)	1 (1)	1 (0)	26 (24)
Normocalcaemic	0	7 (4)	6 (1)	0	13 (5)

Figures in parentheses indicate number of patients with primary hyperparathyroidism.

The application of these criteria is shown in *Table II*. Except in one case all arteriographic examinations and their evaluation have been carried out by one of us (F. E.) before deciding on therapy.

Non-parametric statistical tests have been used with levels of significance of 0·01 and 0·05 depending on the nature of the hypothesis. However, the probability levels actually associated with our findings are given. *Complications*: The only severe and permanent complication was a right-sided hemiplegia in a man aged 58 years. This occurred during the manipulation of a swan-neck catheter ('head hunter' type) in the aortic arch, and as such was unrelated to our method. One case had a transient spasm in the right brachial artery following removal of the catheter. Additionally, 2 patients experienced an unspecific cerebral reaction of short duration, probably related to the contrast medium.

Results

The criterion 'curvolinear arteries' indicating a space-occupying process is, according to Seldinger (1953, 1954), reliable even when the examination is non-selective (*Table II*). In contrast, parenchymal opacification (Doppman et al., 1969) seems only to be of value in the selective technique (i.e. injection into the inferior thyroid artery). Applying these criteria, the angiographic results for each patient were compared with the surgical findings in the 39 patients in whom neck exploration was performed (*Table III*).

Twenty-nine patients showed PHPT. In the remaining 10 patients PHPT was not found (i.e. no parathyroid adenoma or hyperplasia was identified). Among the 29 patients in whom PHPT was confirmed 3 cases had a normal angiograph and are considered 'false negative'. (In *Table III* the column 'true negative' is shown for the sake of completeness.)

In the 10 patients in whom PHPT was not found during neck exploration, angiography was interpreted as positive for parathyroid adenoma. In 6 cases a lymph node or thyroid adenoma was located at the point indicated by the angiograph. From a purely radiological point of view the anatomical diagnosis was correct and these patients are therefore listed under the heading 'true positive'. In 4 cases the angiographic statement could not be confirmed and the patients are listed as 'false positive'.

Table II: ACCURACY OF ANGIOGRAPHIC PARAMETERS IN PREDICTING THE TOPOGRAPHY OF THE PARATHYROIDS IN 39 PATIENTS UNDERGOING NECK EXPLORATION*

* Unilateral examination in 4 patients and bilateral in 35 patients.

It is well known that hyperparathyroid patients may be normocalcaemic for relatively long periods of time. The diagnosis nevertheless may be suspected from other biochemical criteria not discussed in the present paper.

In *Tables I* and *III* the patients are divided into normocalcaemic and hypercalcaemic. Thirteen normocalcaemic patients were subjected to neck exploration, 5 of which revealed PHPT. The distribution of the normocalcaemic patients within the clinical subdivision into four groups is shown in *Table I*. In the 'plausible' group PHPT was confirmed in 4 out of 7 normocalcaemic patients, but in the 'not to be excluded' group this diagnosis was only confirmed in 1 out of 6 normocalcaemic patients.

Concerning the clinical application of angiography, all the patients subjected to neck exploration in the 'not to be excluded' group exhibited a positive angiograph. This differs significantly from the angiographic findings in the remaining 10 patients not subjected to neck surgery, as 7 patients showed a normal angiograph ($P < 0{\cdot}01$, Fisher's exact probability test).

A definite evaluation of the angiographic method has been attempted (*Table IV*). Only the 25 patients with histologically verified PHPT having had preoperative bilateral angiography performed were included. From a taxonomical point of view this is

Table III: COMPARISON OF ANGIOGRAPHIC AND SURGICAL FINDINGS IN 39 PATIENTS UNDERGOING NECK EXPLORATION

Table IV: PREOPERATIVE APPLICATION OF BILATERAL ANGIOGRAPHY IN 25 PATIENTS WITH PROVED PRIMARY HYPERPARATHYROIDISM

	Surgery			
	Positive	Negative	Positive	Negative
Angiography	Non-selective angiography ($n = 15$)		Selective angiography ($n = 10$)	
Positive	9	4	10	2
Negative	6	11	0	8
Sensitivity*	60·0		100	
Specificity†	73·3		80·0	

* Sensitivity is defined as the number of correct positive angiographic findings.

† Specificity is defined as the number of correct negative angiographic findings.

justified. Consequently the evaluation of the specificity of the angiographic method has been based on the angiographic and surgical findings in these 25 patients. As 'unrelated structures' do not add to the diagnosis they have been included in the group of 'false positives' even if they were found to be topically correct at surgery.

Analysing the data from *Table IV* in fourfold tables (Documenta Geigy, 1970) the *selective technique* revealed a highly significant correlation ($P < 0{\cdot}01$) between angiography and surgery, in agreement with the specificity and sensitivity recorded. The specificity and sensitivity achieved by the *non-selective* technique were less favourable and no statistically significant correlation could be demonstrated ($P > 0{\cdot}1$). As to the sensitivity of angiography the size of the adenoma in the present distribution of parathyroid adenomas has to be taken into consideration. The median weight of all parathyroids was 549 mg (range 62–5190 mg, $n = 24$). No difference with respect to size of adenoma between the selective and non-selective technique was found ($P > 0{\cdot}1$, Wilcoxon rank test).

Discussion

The surgical conception that a branch from the inferior thyroid artery might be a guide to a parathyroid adenoma instigated the present investigation. The angiographic method can also demonstrate the parathyroids, as seen from the sensitivity and specificity achieved according to the definitions by Burgess et al. (1962). Selective angiography is superior to the non-selective technique (*Table IV*). The reason for this seems to be the predominance of the inferior thyroid artery in the vascular supply of the parathyroid glands (Alveryd, 1968). In accordance with this assumption we regard it as unnecessary to attempt to catheterize the superior thyroid artery. In fact our figures from selective versus non-selective examinations justify this conclusion.

Kuntz and Goldsmith (1972), combining the angiographic method with thyroid scintigraphy in a series of 21 consecutively examined patients with PHPT, reached a sensitivity of about 70 per cent. However, close examination of their figures indicates that the specificity of their method is only 50 per cent or less. Our technique was not supported by other iconographic procedures. On the other hand, the extremely high sensitivity obtained in the present series is probably not fully reproducible. However, we found our material representative of a parathyroid clinic (*Table I*), and the analysis has been based on two angiographs for each patient in order to achieve complete equality and comparability between the observations.

One might argue that the present investigation reflects differences between selective and non-selective techniques caused by irregularities in the arteries concerned. This interpretation, however, neither alters the results nor affects the conclusions of this study.

Because of the angiographic method's independence of biochemical data we found it valuable to include normocalcaemic patients in the study. No significant differences ($P > 0{\cdot}2$, Fisher's exact probability test) concerning correct or incorrect angiography statements were found between the groups of patients with or without PHPT. These findings were explained by the so-called 'unrelated' structures.

Furthermore, only 5 of the 13 normocalcaemic patients revealed pathologic parathyroids. Compared with the results in the 'not to be excluded' group these figures reflect the influence of angiography on our process of decision. Therefore supporting diagnostic procedures to ascertain hyperparathyroidism in normocalcaemic patients are imperative. The only severe complication recorded was related to manipulation of the catheter in the aortic arch. However, even if the risk is very low (Cronquist et al., 1970) it is a risk that is attached to all methods involving passage of a catheter through the aortic arch.

Parathyroid surgery essentially consists of identification of *all* parathyroid tissues. Therefore, application of current radiographic methods appears to be inconsistent, except for cases subjected to re-exploration.

In our experience the angiographic method requires considerable expertise. For this reason we recommend that the method be restricted to parathyroid centres, and principally to patients selected for re-exploration.

In conclusion the results of non-selective arteriographs are insignificant. Selective arteriography of the inferior thyroid artery is a reliable method for visualization of the parathyroids with both a high sensitivity and specificity.

Nutritional support in the management of external fistulas of the alimentary tract

VICTOR M. KAMINSKY AND MERVYN DEITEL*

SUMMARY

A total of 56 patients with 65 fistulas was treated using one or a combination of three modern nutritional aids. Fifty-two of the fistulas (80 per cent) closed spontaneously and only 7 fistulas (10·8 per cent) required attempts at operative closure. The overall mortality was 7 patients (12·5 per cent), which compared favourably with a 40 per cent mortality in an earlier comparable group which had not received such nutrition.

PRIOR to Dudrick's (1968) classic report, the mortality in patients with fistulas of the alimentary tract ranged from 30 to 50 per cent (Edmunds et al., 1960; Chapman et al., 1964; Halversen et al., 1969). Early resection was recommended for upper small bowel fistulas and expectant treatment for fistulas of the lower bowel as the latter had a higher incidence of spontaneous closure (Edmunds et al., 1960; Bacon and Gennaro, 1969; Lorenzo and Beal, 1969). All agreed that if operation were performed, resection of the involved portion of bowel with anastomosis, if possible, was the treatment of choice.

Chapman et al. (1964) found in their patients with fistulas that those who received more than 3000 kcal/24 hr had a mortality of 12 per cent whereas those who received less than 1000 kcal/24 hr had a mortality of 55 per cent. The former group received the calories by combined intravenous and tube feeding, achieved by passing a tube beyond the fistula or by a feeding jejunostomy.

More recently Voitk et al. (1973), using an elemental diet, had a mortality of 28 per cent, and MacFadyen et al. (1973), treating gastro-intestinal fistulas with intravenous hyperalimentation, had a mortality of 6·4 per cent.

Since 1969 we have used three techniques in patients with major nutritional problems, and in 17 per cent of these patients the indication was alimentary tract fistulas. The results of nutritional support in the management of fistulas have been compared with those in fistulas treated before these methods were available.

Materials and methods

Two groups were reviewed. Group 1 consisted of patients with fistulas treated by modern nutritional methods from July 1969 to December 1973. Group II were patients treated before the introduction of these methods, from July 1965 to July 1969.

Group I

There were 56 patients with 65 external gastro-intestinal fistulas of sufficient magnitude to require special nutritional management. Eleven of these patients were transferred from other hospitals for treatment of their fistulas. There were 34 male and 22 female patients with ages ranging from 16 to 88 years (average 55 years). The distribution of the fistulas is shown in *Table I*.

Table I: SITES OF ORIGIN OF FISTULAS

Origin	Group I* July 1969– Dec. 1973 (54 mth)	Group II† July 1965– July 1969 (48 mth)

Colic	11	7
Total	65	32

* Includes 11 patients transferred from other hospitals for treatment of postoperative fistulas.
† Group studied retrospectively.

Group II

This group consisted of 30 patients with 32 fistulas. As the review of group II was retrospective (group I was a prospective study) only patients whose fistulas had been recorded in the diagnosis, operation notes or as complications could be included (*Table I*). There were 16 male and 14 female patients with ages ranging from 29 to 89 years (average 54 years).

Methods of nutritional support

Routine intravenous feeding solutions contain 5 per cent dextrose, and 3 litres/day would provide 510 kcal, which would have a protein-sparing effect and decrease catabolism by 50 per cent (Gamble, 1958). However, for anabolism and healing in these patients the energy requirements are much greater. Nutritional support was administered by one or a combination of the following methods (*Table II*).

Method I. Intravenous hyperalimentation: Patients received 2000–3000 non-protein kcal/day together with 80–175 g of fortified protein hydrolysate (Deitel, 1973; Deitel et al., 1973). This was infused

* Combined with the other methods during treatment in 31 patients.

continuously via a catheter situated in a large *central* vein (Deitel and McIntyre, 1971) inserted by subclavian puncture. A small constant infusion pump was used to give a flow rate of about 500 mg of dextrose/min (100 mg of protein hydrolysate/min). Strict aseptic precautions were maintained during catheter insertion and dressing changes. Blood was drawn thrice weekly to monitor electrolytes, blood urea nitrogen and blood sugar. This method was used in 55 patients—alone in 24 patients and followed by one of the other two methods in 31 patients.

Method II. The lipid system: Using separate intravenous lines united to a terminal Y-connector attached to a needle in a *peripheral* vein (Deitel and Kaminsky, 1974; Deitel and Syed, 1974) 3 g/kg body weight 24 hr^{-1} of a 10 per cent soybean oil–egg yolk phospholipid–glycerol emulsion (Intralipid) was infused simultaneously with 5 per cent protein hydrolysate in 5 per cent dextrose (*Fig.* 1). The iso-osmolal Intralipid prevented phlebitis in the peripheral vein which may be caused by the hyperosmolal protein hydrolysate-dextrose solution. Electrolytes, vitamins and heparin were added to the protein hydrolysate–dextrose solution. Using this method the patient received more than 2000 non-protein kcal/day and 100–150 g of amino acid. Advantages of this method are that the complications of caval catheters are avoided and hyperosmolar coma does not occur; disadvantages are that the flow rate must be adjusted frequently and forearm movement is limited. The lipid system was used in 7 patients, in sequence with intravenous hyperalimentation and/or elemental diets.

Method III. Elemental diets: These are nutritionally complete, predigested, bulk-free, liquid diets containing simple sugars and properly balanced amino acids requiring no significant digestion by enzymes (Deitel and Kaminsky, 1974; Deitel and Syed, 1974). All essential vitamins, electrolytes and trace minerals are present, as well as ethyl linoleate as a source of essential fat. These diets contain the necessary energy for protein synthesis—more than 150 non-protein kcal/g of nitrogen provided (Moore, 1959). When flavours were accepted orally, the diet was taken as frequent sips to prevent cramping and diarrhoea, and water by mouth was taken *ad libitum* to prevent hypertonic dehydration. When not accepted orally, the diet was delivered via a No. 8 nasogastric tube with a constant infusion pump, with the head of the bed elevated to obviate aspiration. Occasionally the diet was given by a gastrostomy or jejunostomy tube. Elemental diets were used in 30 patients—in sequence with intravenous hyperalimentation and/or the lipid system in 28.

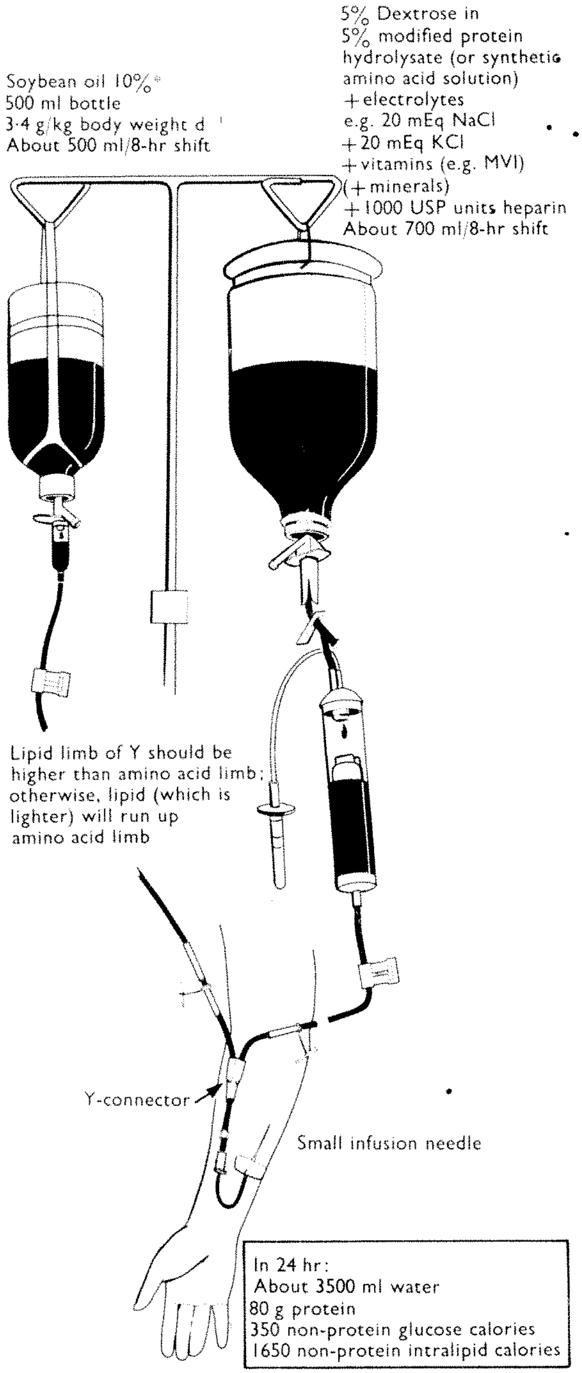

Fig. 1. The lipid system as applied to a 50-kg nutritionally depleted patient. *Intralipid (1·1 Cal/ml for a 10 per cent solution).

Results

Group I

Fifty-two of the 65 fistulas (80 per cent) closed spontaneously with nutritional support (*Table III*). Operative closure was necessary for 7 fistulas (10·8 per cent) in 6 patients, two attempts being

Present series (1974)	1. 1965–69	32	40
	2. 1969–73	65	12·5

unsuccessful with the ultimate death of the patient. The overall closure rate was 86·2 per cent.

The average duration of treatment in the survivors from the time nutritional support was instituted to the time of fistula closure was 44·7 days. Jejunal fistulas took longest to close—more than 200 days in 2 patients, operation being impossible in both (*Fig.* 2).

Seven patients died, giving an overall mortality of 12·5 per cent. Five of the 7 deaths occurred in patients with disseminated carcinoma, which was undiagnosed at the time of commencing nutritional support. If these cases of carcinomatosis, who should not have been managed thus, are excluded the overall mortality was 3·6 per cent.

Group II

Spontaneous closure occurred in 11 of 32 fistulas (34·4 per cent). Operative closure was undertaken for 10 fistulas (31·3 per cent) in 9 patients and was unsuccessful in 2, resulting in the death of the patients. The overall fistula closure rate was 59·4 per cent. The average duration of treatment in the survivors was 79·8 days. Twelve deaths occurre giving a mortality rate of 40 per cent.

Discussion

The recent introduction of nutritional methods h reduced the high mortality and morbidity associat with external gastro-intestinal fistulas (*Table I* Although we emphasize the importance of nutritio an aggressive policy towards control of the fistula ar associated sepsis was also pursued. This includ the introduction into the fistula of a catheter attach to effective suction to prevent pooling. The suctic catheter was slowly withdrawn and replaced by narrower catheter. This resulted in closure of t fistula or the formation of a well-defined tract ov which an ileostomy bag could be applied. Occasional the patient was placed prone on a Stryker bed afford free drainage and to prevent skin digestion.

The surrounding skin was protected with kara gum powder, karaya and glycerin, aluminium past tincture of benzoin, or cod liver oil–zinc oxide cor pound barrier cream (Desitin). In our experien a liberal amount of the latter cream was the mo effective, as the enzyme-rich fluid flowed over t cream without digesting the underlying skin. The debilitated patients were placed on pulsating a mattresses to avoid decubitus ulcers and mobilized much as possible to promote anabolism. Generaliz sepsis was controlled with the appropriate antibiotic and localized abscesses were drained when diagnose

Factors which contributed to prolonged fistu drainage were: (1) distal bowel obstruction, ir tability, inflammation or abscess; (2) previo irradiation to the area; (3) underlying granulomato bowel disease; (4) bowel immediately adjacent to skin with a very short fistulous tract; (5) metallic mercury (from ruptured balloon of a long intestinal tube) in the fistulous tract; (6) reactive foreign bodies, e.g. heavy silk sutures. The fistula could often be outlined radiographically on liquid contrast-medium gastro-intestinal studies. However, the introduction of radio-opaque liquid into the external opening of the fistula was the most successful way of identifying its nature and origin. Conservative treatment was abandoned and operative closure performed with distal obstruction, wide breakdown or complete disruption of an anastomosis.

Most fistulas were treated initially with intravenous hyperalimentation, while electrolyte and fluid balances were restored. At the same time adequate calories and amino acids for protein synthesis were supplied, while suppression of gastro-intestinal secretions (Hamilton et al., 1971) caused a rapid decrease in fistula output. Those who eventually required surgery were in a better nutritional state to withstand operation. Only one patient developed catheter sepsis (*Staphylococcus aureus*), which resolved immediately on removal of the catheter (Sanderson and Deitel, 1973). Another patient developed non-ketotic hyperosmolal coma (Deitel et al., 1973; Sanderson and Deitel, 1974), which was treated with insulin and rehydration without ill effect to the patient. No patient died from the nutritional treatment.

Although fistulas often heal more rapidly on intravenous hyperalimentation than on elemental diets, many potential dangers of the former are removed by changing to elemental diets when fistulas are close to being solidly healed. In situations where intravenous hyperalimentation is difficult to institute, e.g. the proximity of a burn scar or a tracheostomy, the peripheral lipid system is valuable.

The treatment of resistant malignant ascites by insertion of a peritoneo-atrial Holter valve

A. V. POLLOCK*

SUMMARY

Holter valves have been used in 9 cases to drain ascites, and in 1 case a pleural effusion, into the superior vena cava. All these effusions were due to malignant disease. Three patients died before the results of the operation could be assessed and in 1 case ascites rapidly recurred. Five patients were relieved until death from their primary disease. One patient died 3½ years after insertion of the valve, but ascites had returned—probably as a result of recurrent blockage of the valve by particulate matter.

THE formation of ascites (like that of tissue fluid) depends on the balance of hydrostatic and osmotic pressures between capillaries, tissue spaces and the peritoneal cavity, the effective functioning of capillary and peritoneal semipermeable membranes and the free flow of lymph.

The commonest causes in the United Kingdom are cirrhosis of the liver and secondary carcinoma of the peritoneum. Non-operative treatment may eliminate the ascites in both conditions, but paracentesis may be needed and, if repeated, causes distress to the patient and depletion of protein.

During the past 3 years the author has operated on 10 patients whose malignant effusions were resistant to orthodox treatment, placing a Holter valve subcutaneously between the peritoneal (9 cases) or pleural (1 case) cavities and the superior vena cava or right atrium. The pressure differential is sufficient to ensure a continuous centripetal flow of fluid without manipulation of the valve.

Methods

The only indication for operation is the resistance of ascites to conservative treatment, and the result is that many patients are operated on at a terminal stage of their disease. As a rule, light general anaesthesia is used, but one valve was inserted under local infiltration anaesthesia.

The patient is placed supine on the operating table with his arms by his sides. A 3-cm incision is made just below the tip of the ninth rib and deepened to the peritoneum, which is punctured and ascitic fluid aspirated. (Early in the series all the fluid was not removed, and as a result 1 patient developed hypervolaemic heart failure and another suffered a massive leak of ascitic fluid into the subcutaneous tissues.)

The inlet tube of a low-pressure Holter valve is placed in the peritoneal cavity and the abdominal wall sutured around it. The valve and the outlet tube are connected and the valve positioned over a convenient rib, which allows detection of patency postoperatively. A new incision 5 cm long is made below the outer half of the clavicle on the same side. The pectoralis major muscle is split and divided and the pectoralis minor divided to give access to the first and second parts of the axillary vein. A pair of sigmoidoscopic biopsy forceps is thrust subcutaneously from the upper to the lower incision and the outlet tube of the valve drawn into the upper wound. The cephalic vein is opened near its junction with the axillary vein and the tube manipulated through this opening into the axillary vein, subclavian vein and superior vena cava until the tip lies opposite the right atrium. Its position is verified radiographically and the wounds closed.

During the first few postoperative days diuretics are given in large doses, as fluid overloading is common.

Results (*Table I*)

The patient operated on for a massive malignant pleural effusion due to carcinoma of the breast (*Case* 1) was relieved of the effusion, but died of carcinomatosis after a month.

The remaining 9 patients (*Cases* 2–10) had peritoneal carcinoma, the primary growths being in the breast (2), stomach (1), pancreas (1), ovary (2), bladder (1) and unknown (2).

The ascites of 8 of these 9 patients was temporarily relieved by operation. The ninth patient (*Case* 9) was *in extremis* and his ascites had rapidly reaccumulated after two paracenteses. The valve was inserted in the usual way but failed to function, and X-rays showed the tip of the outlet tube lying in the right ventricle (operative X-rays had been omitted in this case). The outlet tube was therefore shortened by 6 cm and the system functioned. He died in coma 2 days later and at autopsy the valve was patent.

Of the remaining 8 patients, 3 died of malignant disease within 28 days of insertion of the valve, 3 died between 1 and 5 months postoperatively without reaccumulation of the ascites, 1 died 4 months later with recurrent ascites and 1 patient died 3½ years after operation with recurrent ascites (*Case* 2).

Case report

Case 2: In July 1968 Mrs M. G., aged 51 years, had a left extended simple mastectomy for scirrhous carcinoma with involved axillary nodes. In 1969 skin nodules were found on the abdomen and back. Biopsy of one of these showed spheroidal celled carcinoma, and X-rays revealed disseminated

sclerotic bone metastases. Endocrine surgery was contemplated, but the patient's general health was so good that this was not advised. She continued symptom-free until December 1970 when she developed oedema of the ankles, followed by ascites. She felt ill and, for the first time, was unable to go about her normal affairs.

Following paracentesis in January 1971 the ascites reaccumulated within 2 weeks despite large doses of frusemide. A peritoneo-atrial Holter valve was therefore inserted in February 1971. Postoperatively she had a massive diuresis and lost 6 kg in weight.

She maintained good health for over 2 years, when ascites recurred. Chest X-ray showed no abnormality apart from sclerotic metastases in the ribs.

Under general anaesthesia the fluid was drained from the peritoneal cavity and the valve removed, leaving patent inlet and outlet tubes in position. The valve itself was found to be blocked at its entrance by a minute piece of white tissue. This was cleared out with a needle and the valve reinserted, but it failed to function and ascites reappeared within a month. A new valve was put in, but again blocked within a month. Periodic paracentesis was continued until the patient's death 3¼ years after insertion of the valve. Autopsy showed no pulmonary metastases.

Discussion (*Table II*)

Most cases of cirrhotic ascites can be controlled by a strict regimen of diuretics, sodium restriction, high protein diet and avoidance of alcohol. Sherlock (1971) reported 112 cirrhotic patients and failed to control ascites in only 6, none of whom survived a year.

Malignant ascites, on the other hand, responds poorly to treatment. Cytotoxic drugs (MacGregor et al., 1969), radiotherapy, hormones and endocrine surgery have not always been successful. Many patients are condemned to repeated paracenteses which deplete albumin reserves and have a demoralizing and weakening effect. This is particularly true of those with disseminated carcinoma of the breast who may live for several years after the development of ascites.

Many methods of surgical relief of cirrhotic ascites have been described (Crosby and Cooney, 1946; Welch et al., 1964; Fish et al., 1968; Schreiber et al., 1968; Steigmann et al., 1968; Hermann and Taylor, 1971; Sein, 1973; Parbhoo et al., 1974), but surgical treatment of malignant ascites has attracted less attention.

Ferguson (1943) removed the left kidney and anastomosed the renal pelvis to the peritoneum, and Mulvany (1955) treated 7 patients with malignant and 3 with cirrhotic ascites by draining the peritoneal cavity into the bladder. The problem of protein loss was not solved by these operations.

Many operations have been designed to drain ascitic fluid into the general circulation. In 1907 Ruotte successfully anastomosed the divided proximal end of the long saphenous vein to the peritoneum in the lower abdomen so that ascitic fluid drained into the femoral vein. Unfortunately, later workers found that the anastomosis closed and the saphenous vein clotted. Schnee (1955) sought to overcome this difficulty by using a 'button' which traversed the abdominal wall and on to which he tied the saphenous vein.

Crosby and Cooney (1946) recorded 6 patients with ascites (5 cirrhotic and 1 due to constrictive pericarditis) treated by insertion of a glass tube or 'button' to lead ascitic fluid through the anterior abdominal wall into the subcutaneous tissues whence it was absorbed. One patient died of peritonitis, but the other 5 were relieved of their ascites. El-Toraei (1961) reported 18 patients whose cirrhotic ascites was treated by the construction of a pleuroperitoneal fistula. Three died postoperatively and 3 were 'cured', but a pleural effusion remained in all the cases.

In 1962 Smith published a preliminary communication on the use of a Spitz–Holter valve in a patient who had been subjected to numerous paracenteses for resistant cirrhotic ascites. The inlet tube of the valve was inserted into the peritoneal cavity, the valve lay in the subcutaneous tissue over the symphysis pubis and the outlet tube was passed into the long saphenous vein and thence to the inferior vena cava. Six months later the patient was well.

Experience of the 10 cases described in this paper leads the author to believe that malignant ascites can usually be controlled in the same way as hydrocephalus by draining the fluid through a one-way valve into a central vein. The operation has not previously been used for the palliative treatment of malignant ascites, possibly because of the fear of dissemination of cancer cells into the general circulation. However, the improvement in the health of *Case* 2 following insertion of the valve, together with the absence of lung metastases more than 3 years later, makes this a doubtful objection.

A more valid criticism of the method is the possibility that the valve will become obstructed by particulate matter in the ascitic fluid. This is thought to be the cause of the late failure in *Case* 2 and the complete failure in *Case* 10, when the ascitic fluid reaccumulated within a month of insertion of a valve. The latter patient died 3 months later and examination showed that the peritoneal inlet tube was not only blocked by a small plug of fibrin and cancer cells but also acutely kinked. In future a reservoir valve of the Pudenz type instead of the classic Holter valve will be used.

Most of the patients reported here were at a terminal stage of their disease, and 4 of them did not live long enough to benefit from the relief of their ascites. The operation does, however, have a place in the management of cancer patients whose end would otherwise be made more miserable by rapid reaccumulation of fluid.

Abdominal approach for the ligation of bleeding oesophageal varices

STANLEY S. MILLER*

SUMMARY

The conventional surgical treatment of bleeding oesophageal varices in the emergency situation is based upon the Boerema-Crile operation of transthoracic oesophagotomy and ligation of the varices. This and the other methods of treatment of this condition in current practice are discussed.

Two cases are reported in which a transabdominal oesophagogastrotomy was used to approach the site of bleeding. This operation is described and the theoretical and practical advantages it appears to offer over the standard approach are considered.

EMERGENCY surgery to stop bleeding from oesophageal varices carries a high mortality, but death is almost inevitable if bleeding is allowed to continue. The mortality of a single bleed from oesophageal varices has been reported as over 50 per cent (Garceau et al., 1963). Of the survivors from this initial haemorrhage, 50 per cent will die within 1 year from further massive bleeding (McDermott, 1972). If bleeding persists or recurs despite adequate conservative measures it has been advocated that direct control be achieved by transthoracic oesophagotomy and ligation of the varices (Boerema, 1949; Crile, 1953; Linton and Warren, 1953) (*Fig.* 1). The mortality and morbidity of this operation, however, remain high because these are poor risk patients, often desperately ill.

In a series of 58 patients treated by the Boerema–Crile operation reported by Rothwell-Jackson and Hunt (1971) there were 25 early postoperative deaths and 13 late deaths. It was thought, however, that, since most if not all of these patients would have died without surgery, 'it is not unreasonable to consider the results of surgery in these circumstances in terms of salvage (29 per cent) rather than mortality'.

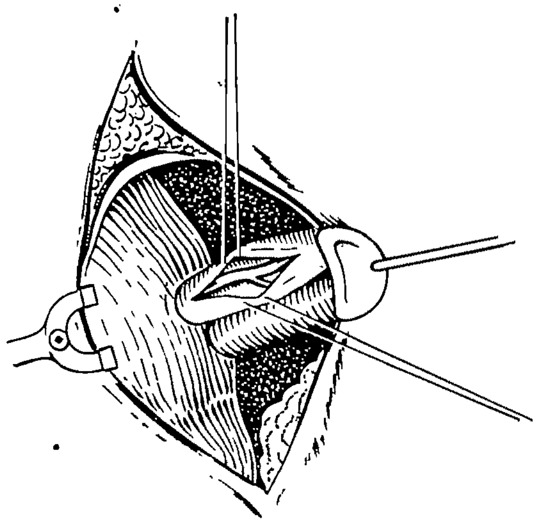

Fig. 1. Transthoracic ligation of oesophageal varices.

In the 2 cases reported here direct ligation of bleeding oesophageal varices by transabdominal oesophagogastrotomy was performed. This proved to be a safe practical method of approaching the bleeding source and to have certain advantages over the normal transthoracic operation.

Case reports

Case 1: E. F. a male aged 44 years. In May 1972 when this man was investigated for anaemia due to gastro-intestinal bleeding, a duodenal ulcer was demonstrated radiologically. It was also noted that there was distortion of the fundal mucosal pattern, suggestive of varices, although it was considered that a similar appearance could be produced by hypersecretory gastric mucosa. Endoscopy revealed hypertrophic gastritis but no convincing evidence of varices. Liver biopsy, however, showed the features of a micro-nodular cirrhosis. He was also found to be hypertensive and diabetic.

The patient remained well until emergency admission in November 1972 with a small haematemesis. Although initially stable, shortly after admission he suddenly vomited several pints of fresh blood and had a severe hypotensive episode. It seemed clear that urgent surgical intervention was indicated, and following a short period of preoperative preparation a laparotomy was performed.

An abdominal approach was selected because of the possibility that the source of bleeding was from a posterior duodenal ulcer. In view of the continuing haemorrhage and the previous equivocal findings it was considered that endoscopy might only produce further delay without necessarily contributing to the diagnosis.

At operation the presence of cirrhosis was confirmed but the source of bleeding was not immediately apparent. A small distal gastrotomy was thus made and through this, active bleeding was seen to be coming from the upper part of the lesser curve, the duodenum being clear. As the source seemed certain to be variceal a separate oesophagogastrotomy was fashioned (*Fig.* 2). This was facilitated by dividing the peritoneum and hiatal membrane over the abdominal part of the oesophagus and with finger dissection bringing the lower thoracic oesophagus into the abdomen. A portion of Paul's tubing was passed around the oesophagus to act as a retractor, as when performing a truncal vagotomy. The triangular ligament was not divided as it is felt that the left lobe of the liver is more easily managed if fixed by this structure and lifted upwards with a large Dyball retractor.

The peri-oesophageal veins were transected and, on opening the oesophagogastric junction between stay sutures, the source of bleeding was found to be a varix on the lesser curve aspect of the cardia. This and two other columns of varices were obliterated by running silk sutures, commencing on the gastric fundus and extending 7–8 cm up the oesophagus. This was facilitated by holding the margins of the incision open with

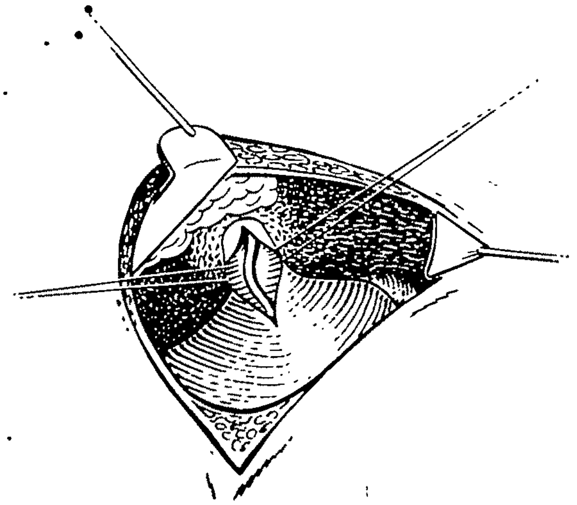

Fig. 2. Transabdominal ligation of oesophagogastric varices.

light tissue forceps. When the bleeding was satisfactorily under control the incision was closed with inner continuous chromic catgut and interrupted seromuscular silk sutures. The original gastrotomy incision was closed in a similar manner.

At the completion of the procedure a noxytiolin washout of the peritoneal cavity was performed. It has been our practice to do this after operations on all forms of acute gastroduodenal haemorrhage, as the site of operation inevitably becomes contaminated with blood clot which may have been in an achlorhydric stomach for several days and mixed with swallowed saliva. The abdomen was then closed in layers with catgut, nylon deep tension sutures and peritoneal drainage.

The patient made an uncomplicated postoperative recovery except for an early period of confusion which was attributed to ammonia absorption from the blood in the bowel. A Gastrografin swallow and meal showed no leakage and the chest X-ray remained clear throughout. He is well now 1 year after operation and is being considered for a portacaval shunt.

In this case an abdominal incision was chosen because of the possibility that the source of bleeding was in the duodenum. When the bleeding was found to arise from oesophageal varices little difficulty was encountered in approaching the lower end of the oesophagus in this way and good exposure was obtained.

Case 2: H. M., a female aged 54 years with no previous medical history, was admitted with a 24-hour history of haematemesis following the ingestion of aspirin. There was little of note on examination or investigation except for a haemoglobin level of 5·49 g per cent. The blood loss was restored with 6 units of blood overnight and at first there was apparently complete stabilization. However, a large fresh haematemesis the next morning led to urgent laparotomy. This was carried out via a paramedian incision and oesophageal varices were found, one of which was bleeding at the level of the cardia. The haemorrhage was controlled and the varices obliterated through an oesophagogastrotomy, as described in *Case* 1. On this occasion a vagotomy was performed in order to mobilize the oesophagus further into the abdomen. Histological examination of a liver biopsy revealed primary biliary cirrhosis, a diagnosis which was supported by a positive anti-mitochondrial antibody test and a raised serum IgM level.

The patient made an uncomplicated postoperative recovery and remains well now 6 months after operation.

In this case there was haemorrhage to a degree requiring operation but no definitive preoperative diagnosis. An oesophagoscopy could have been used prior to exploration but experience with *Case* 1 gave confidence that if bleeding varices were encountered then control could be achieved from below. This in fact proved to be the case.

Transabdominal oesophagogastrotomy versus transthoracic oesophagotomy

There are several theoretical and practical reasons why transabdominal oesophagogastrotomy may give better results than transthoracic oesophagotomy.

1. *Oesophageal disruption*

In the transthoracic approach the oesophagus is incised at its weakest part. In spontaneous rupture of the oesophagus the tear, longitudinal and 1–8 cm in length, is most often on the left side just above the diaphragm. This coincides with the incision described in the Boerema–Crile operation. It is generally regarded that at this point the oesophagus is intrinsically weak and has least support from surrounding tissues. This view is reinforced by the fact that while there has been only one reported case of spontaneous rupture of the abdominal oesophagus (Strauch and Lynch, 1965) there are well over 100 involving the lower thoracic oesophagus (Tesler and Eisenberg, 1963).

The inherent weakness at this point together with other factors, such as delay in wound healing, may contribute to the disruptions which occur following the Boerema–Crile procedure. Oesophageal disruption was a major postoperative problem in the series presented by Rothwell-Jackson and Hunt in 1971. Of 58 transthoracic oesophagotomies, in 10 there was breakdown of the oesophagotomy incision and none of these patients survived.

2. *Morbidity of a thoracotomy*

These operations are carried out as emergencies on unprepared patients, often with pre-existent chronic heart and lung disease. It seems probable that an abdominal incision might have a lower incidence of chest complications than a thoracotomy. In the series of Rothwell-Jackson and Hunt (1971) pneumonia was a cause of early and late postoperative deaths, and non-fatal complications included surgical emphysema, pleural effusion and haemothorax.

There are also advantages in the employment of approaches and techniques which are in day-to-day use. As most of these emergencies are dealt with by general surgeons a laparotomy would appear to be the most logical approach. Further, since the introduction of truncal vagotomy in the treatment of duodenal ulceration (Dragstedt et al., 1947), surgeons have become more familiar with the abdominal approach to the oesophageal hiatus.

3. *Coexistent gastroduodenal pathology*

Clarke et al. (1958) reported a frequency of associated cirrhosis and peptic ulceration as high as 25 per cent. In a study of patients dying from massive gastro-intestinal haemorrhage, Chalmers et al. (1952) found that 27 per cent with known liver disease bled to death from a cause other than oesophageal varices.

There is thus a strong likelihood of coexistent gastroduodenal disease, which if not the actual source of the acute haemorrhage may merit definitive treatment in its own right. Failure to do this will add to the list of postoperative complications. Recognizing the high incidence of peptic ulceration in cirrhotic patients, Rothwell-Jackson and Hunt (1971) latterly added thoracic vagotomy to the Boerema–Crile procedure, but there is little doubt that a laparotomy allows for a more complete assessment of the situation than does an approach through the chest. In their series there were early postoperative deaths from a perforated gastric ulcer, carcinoma of the stomach and a bleeding gastric varix. In Crile's original description of the technique used in 9 cases of variceal bleeding (Crile, 1953) there were 2 further episodes of bleeding. In 1 patient this originated from a gastric ulcer.

4. *Direction of flow and pressure in oesophageal varices*

The collateral route, provided by the oesophageal varices, is fed mainly from below by the vasa brevia and by reversal of flow in the left gastric vein. It seems rational to ligate the varicose vessels as close as possible to the source of high venous pressure. Thus, ligation in the oesophagus may leave gastric varices still exposed to a high venous pressure. If varices should be left at a higher level in the oesophagus after oesophagogastric ligation these are liable to be exposed to a low systemic venous pressure and thus unlikely to produce catastrophic haemorrhage. The level of the bleeding point is variously given in the literature but in most it is stated that it will be close to or below the cardia (Hunt, 1964; McDermott, 1972).

5. *Unknown source of bleeding*

The precise diagnosis of the source of upper gastrointestinal tract haemorrhage before operation can be often difficult and sometimes impossible. It may be necessary to explore patients when the diagnosis is still in question. Adoption of the transabdominal approach to oesophageal varices means that most contingencies will be covered by a laparotomy.

Discussion

Haemorrhage from oesophageal varices is invariably serious and often fatal. Death is either from exsanguination or the precipitation of hepatic failure. If the stress of a major emergency surgical procedure is added to the shock produced by massive haemorrhage, the likelihood of fatal hepatic decompensation is increased.

The mortality of emergency operation in the treatment of uncontrolled haemorrhage is very high. Thus, emergency portacaval anastomosis carries a mortality of 50–60 per cent (O'Sullivan and Payne, 1956; Wantz, 1957). Emergency gastric transection (Tanner, 1961) is a formidable operation and there is a high incidence of recurrent haemorrhage, so that it cannot be regarded as a definitive procedure (O'Donnell and Maloney, 1968). There are similar objections to emergency oesophageal transection, the operation of choice at the Royal Free Hospital. In a recent report from that hospital, George et al. (1973) noted an operative mortality rate of 53 per cent in patients with cirrhosis. To date, transthoracic ligation has been considered the best emergency procedure from the point of view of haemorrhage control, but this has a mortality of about 40 per cent (Rothwell-Jackson and Hunt, 1971).

Ideally, if haemorrhage could be controlled with surety by conservative means, liver function might be improved and an elective shunt procedure carried out in optimal conditions with more acceptable mortality figures. The importance of non-operative control of bleeding has been long recognized, but of the methods tried, none has been entirely satisfactory, including intravenous Pitressin (Shaldon and Sherlock, 1960), the Sengstaken tube (Vorrhees, 1959) and oesophagogastric cooling (Wangensteen et al., 1963). More encouraging results have recently been reported by the use of sclerosant injection therapy (Hunt et al., 1969). In 100 consecutive patients control was achieved in 90 per cent of cases with a mortality of less than 20 per cent. Others, however, have found visualization of the injection site difficult when the bleeding is profuse (Rothwell-Jackson and Hunt, 1968), and it can be difficult for the inexperienced.

The transabdominal route for the ligation of oesophageal varices was described in 1956 by Welch (1956), who used it in 5 patients with cirrhosis of the liver and bleeding, noting that control of haemorrhage was complete in all. Three patients died in liver failure and this he attributed to poor liver function and the lateness of surgery. In each of these 3 cases, haemorrhage was initially considered to have been controlled with the Sengstaken tube, but there was persistent or recurrent bleeding necessitating late surgical intervention.

Criticism of the transabdominal approach has mainly been that it can be difficult to negotiate an enlarged liver. In the cases reported here a large deep retractor was used to lift the liver away from the oesophagus. Welch (1956) divided the left triangular ligament and approached the oesophagus over the top of the left lobe of the liver, which was retracted downwards and to the right. Difficulty will also be encountered if attempts are made to perform a transgastric ligation of varices, and it should be emphasized that for easier and more effective control an oesophagogastrotomy incision must be made. Therefore if a diagnosis of a bleeding oesophageal varix is made through the initial small pylorotomy this should not be extended proximally but closed later as a pyloroplasty, and a separate incision made over the cardia. Vagotomy is indicated to facilitate mobilization of the lower oesophagus and because of the high incidence of peptic ulceration in cirrhosis. It also reduces gastric acidity which may be incriminated as a factor in recurrent variceal haemorrhage. Consequently it is felt that pyloroplasty should be added to this operation.

Choice of suture material

In the cases reported here non-absorbable suture material was used to obliterate the varices, although in most reported cases catgut has been advocated. There is some uncertainty from experimental work about the duration of integrity of catgut in the stomach (Howes, 1928; Holder, 1946), and our feeling has been that non-absorbable material provides a more certain method of ligation in the short term, accepting the possibility that a continuous stitch of this material may later cause symptoms of ulceration (Tanner, 1951). It may be that polyglycolic acid (Dexon) will prove to be a more satisfactory suture material in this situation and we are currently investigating this possibility.

Conclusions

Transabdominal oesophagogastrotomy and ligation is a sure method of haemorrhage control well within the competence of a general surgeon and, for the reasons outlined above, may have advantages over the transthoracic approach.

Once it is apparent that there is massive gastrointestinal haemorrhage the patient is best served by urgent operation with no time wasted on medical measures, which can be time-consuming and uncertain as far as the control of haemorrhage is concerned. Endoscopy is unnecessary if the transabdominal approach is chosen. Haemorrhage from oesophageal varices should be regarded in the same way as any other situation where there is massive bleeding.

The abdominal approach, we feel, offers a method of control which can be swiftly performed with a minimum of upset to the patient. Although our experience has been of only 2 cases we have been impressed by their smooth uncomplicated postoperative recovery. Like the transthoracic approach, however, it should not be regarded as a definitive procedure and the patient should probably be considered for a portacaval shunt on recovery.

Acknowledgements

I am grateful to Mr P. F. Jones for guidance in the management of these patients and to Professor G. Smith and Dr P. W. Brunt for helpful criticism in the preparation of this article. I thank Mr Nigel Lukins for the preparation of the illustrations.

NEW
Praxilene
vasoactivator
INJECTABLE
RELIEVES REST PAIN

NEW

for peripheral vascular disorders

Praxilene

vasoactivator

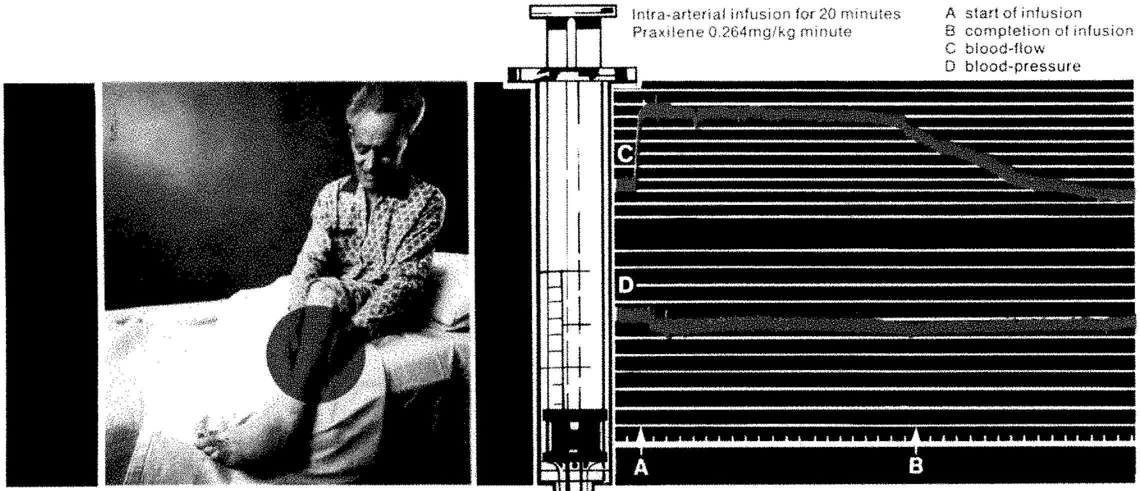
INJECTABLE

RELIEVES REST PAIN

by flushing out pain producing metabolites

by improving blood-flow – without affecting blood-pressure

by a unique metabolic activity



Fast relief

Praxilene administered parenterally (Intra-arterial; Intravenous; Intramuscular) can give relief of pain within as short a time as one week, in many cases.

Prolonged relief

Relief of pain is prolonged: at the same time the collateral circulation is given the opportunity to develop, resulting in an improved blood supply to the affected limb.

Praxilene has produced excellent results because it has a very wide safety margin and the dosage can be individually tailored to the severity of the disorder.

Praxilene: Unique Vasoactivator

Praxilene: Naftidrofuryl: available as 40mg ampoules and 100mg capsules.

Full prescribing information and dosage schedule on request

Decreased incidence of indomethacin-induced gastric ulceration in rats by bile duct diversion

FOROOGH S. ABTAHI AND BIJAN DJAHANGUIRI*

SUMMARY

Gastric mucosal ulceration was produced in rats following intraperitoneal injection of indomethacin (40 mg/kg). The incidence of ulcerations was progressively reduced as the bile flow was diverted progressively distal to the ampulla of Vater. It is suggested that bile reflux into the stomach may play a part in the pathogenesis of indomethacin-induced gastric ulceration in rats.

INDOMETHACIN has been known to produce gastric mucosal ulceration in man (Norcross, 1963) and laboratory animals (Menguy and Desbaillets, 1967; Djahanguiri, 1969). The mechanism of the ulcerogenic action of this substance is not well understood. According to Menguy and Desbaillets (1967) indomethacin administration in the dog decreased the rate of mucous secretion and lowered the concentration of carbohydrate, particularly sialic acid and L-fucose, in the mucosubstance. Nicoloff (1968) demonstrated that gastric juice output from vagally denervated fundic pouches is decreased and parietal cell population and mucosal thickness are essentially unchanged after indomethacin administration. A selective increase in gastric blood flow was also noted in dogs ingesting the drug (Edlich et al., 1970). Kent et al. (1969) showed that pretreatment of animals with neomycin, polymycin B and bacitracin reduced the severity of indomethacin-induced ulceration in the stomach, jejunum and ileum. They concluded that the intestinal flora plays a role in the development of ulcers.

We have previously demonstrated that indomethacin-induced gastric ulceration in the rat is prevented by bile duct or pylorus ligation (Hemmati et al., 1974). The same results have been obtained in rats treated with aspirin (Djahanguiri et al., 1973). Therefore we suggested that bile reflux into the stomach may play a part in the pathogenesis of aspirin or indomethacin-induced gastric mucosal lesion.

In the present investigation we have studied the effect of bile drainage into different sites of the small bowel on the incidence of gastric ulceration produced by indomethacin in rats.

Materials and methods

Sprague-Dawley rats of both sexes weighing 180–250 g were used. They were fasted for 24 hours before the experiment, but had free access to water. The animals were divided into seven groups of 20 rats each. The animals in the first group were left untouched. The remaining animals were anaesthetized with ether and their abdomen opened. The second group was considered as sham operated and the abdomens of the animals in this group were closed. In groups 3, 4, 5, 6 and 7 a polyethylene cannula was inserted into the bile duct so that the pancreatic juice flow was not impaired. The other end of the cannula was inserted into the small bowel 0, 2·5, 5, 7·5 and 10 cm respectively distal to the ampulla of Vater. Both ends of the cannula were tied off gently, providing free passage of both bile and small bowel contents. The animals in each group were divided into two subgroups of 10 rats, providing control and experimental groups. Ten minutes after the animals recovered from anaesthesia they received either saline or indomethacin. The control animals received 1 ml/200 g body weight of 0·85 per cent saline solution. Indomethacin was suspended in 0·85 per cent saline solution and administered to the experimental rats at a dose of 40 mg/kg in a volume of 1 ml/200 g body weight. Injections were made by the intraperitoneal route. Four hours after saline or indomethacin administration the animals were sacrificed by a blow on the head. The stomachs were opened and inspected for the presence of ulceration by an observer who was not aware of the experimental protocol, in order to exclude bias. Although a number of investigators have used different criteria as evidence of ulceration, we considered macroscopically necrohaemorrhagic spots larger than 2 mm in diameter as evidence of ulceration. The frequency of these spots, found in the glandular part of the stomach, ranged from 2 to 15. Microscopic examination of ulcer-containing stomachs, chosen at random, confirmed the presence of ulceration in the mucosal layer, rarely reaching the muscularis mucosa, and always accompanied by oedema, necrosis, haemorrhage and infiltration of inflammatory cells. The macroscopic and microscopic findings in both techniques, in positive cases, were the same; χ^2 test was used for the statistical analysis of the data (Armitage, 1971).

Results

None of the control animals had a gastric mucosal lesion. Indomethacin produced ulceration in 100 per cent of the unoperated and sham-operated animals. The percentages of rats with ulceration in the operated animals were 100, 80, 50, 30 and 10 per cent in

groups 3, 4, 5, 6 and 7 respectively (*Fig.* 1). The incidence of indomethacin-induced ulceration is significantly ($P < 0{\cdot}001$) reduced in groups 5, 6 and 7 compared with groups 1, 2 and 3. The results show that the incidence of ulceration was progressively reduced as the bile flow was diverted progressively distal to the ampulla of Vater.

Discussion

The results of the present experiment show that exclusion of bile reflux from the stomach prevents the appearance of indomethacin-induced gastric ulceration in rats fasted for 24 hours. Although this experimental model of drug-induced gastric ulceration has not been proved to be similar to human acute gastritis, the operation performed in this experiment is similar to that reported by Scudamore et al. (1973), who successfully treated 13 patients with bile reflux gastritis with a Roux-en-Y type of operation to prevent bile reflux. They anastomosed the biliary branch of the Y to the jejunum 50–60 cm distal to the gastrojejunal anastomosis. We have previously observed that bile duct or pylorus ligation prevents indomethacin-induced as well as aspirin-induced gastric lesions in rats. Moreover, Capper et al. (1966) have injected barium into the duodenum and have studied duodenal reflux radiologically. Nineteen out of 29 patients with gastric ulcer had duodenal reflux compared with none of the 15 control subjects.

From these findings it is suggested that bile reflux plays a part in the pathogenesis of indomethacin-induced gastric ulceration in rats. The effect of bile in the stomach is not known. Bile salts have been shown to be cytolytic, to damage the gastric mucosa and to release gastrin (Nahrwold, 1972). However, the precise mechanism whereby the presence of bile in the stomach promotes the pathogenesis of gastric ulceration following indomethacin administration is not clear.

The aetiology of hypocalcaemia in acute pancreatitis

JOHN R. CONDON, DAVID IVES, MICHAEL J. KNIGHT AND JOHN DAY*

SUMMARY

Plasma calcitonin, glucagon and parathyroid hormone were measured in patients with acute pancreatitis.

Plasma calcitonin was not detectable in 6 specimens obtained from the hypocalcaemic patients.

Plasma glucagon values were similar in patients with acute pancreatitis and control subjects and were unrelated to hypocalcaemia, which was not even induced by glucagon infusion.

High or rising parathyroid hormone levels were noted in association with hypo- and normocalcaemia, suggesting that parathyroid hormone rises and maintains plasma calcium within normal limits. Plasma parathyroid hormone was, however, undetectable in 8 patients with prolonged hypocalcaemia. Deficiency of parathyroid hormone due to its destruction by proteolytic enzymes or because of parathyroid gland exhaustion is suggested as the major factor inducing persistent hypocalcaemia in acute pancreatitis. Administration of parathyroid hormone should, therefore, be considered in patients with acute pancreatitis when hypocalcaemia does not respond to intravenous calcium therapy.

HYPOCALCAEMIA occurring in patients with acute pancreatitis was originally thought to be due to the deposition of calcium in areas of fat necrosis (Langerhans, 1890; Edmondson and Fields, 1942). More recently, Paloyan, Lawrence et al. (1966) suggested that hyperglucagonaemia occurred in acute pancreatitis; this might induce hypocalcaemia either by releasing calcitonin (Pickleman et al, 1969; Shieber et al., 1969) or by directly inhibiting bone resorption (Stern and Bell, 1970; Tanzer et al., 1970). A third possible cause of hypocalcaemia in acute pancreatitis is failure of parathyroid hormone to mobilize calcium from bone (Hernandez et al., 1961). This could be due to defective secretion of the hormone by the parathyroid glands, chemical degradation and inactivation of the hormone by proteolytic enzymes in the peripheral circulation or lastly inhibition of parathyroid hormone-stimulated bone resorption by glucagon and/or calcitonin (Raisz et al., 1968; Condon, 1971).

We have investigated these possible mechanisms by measuring circulating parathyroid hormone, glucagon, calcitonin and calcium in patients with acute pancreatitis. The effect of glucagon on calcium metabolism was also studied in patients with acute pancreatitis treated with the hormone (Knight et al., 1971; Condon et al., 1973).

Materials and methods

Plasma calcium was determined by atomic absorption spectrophotometry.

Parathyroid hormone was measured by radioimmunoassay. The antisera used was raised in guinea-pigs against bovine parathyroid hormone (B W 211/32); an uncoated charcoal technique was used.

Glucagon was measured by radio-immunoassay using spherocil-extracted samples and a specific antiserum for pancreatic glucagon (Day et al., 1972).

Calcitonin was determined by Dr G. V. Foster by radio-immunoassay (Clark et al., 1969).

Thirty patients with acute pancreatitis were investigated. The diagnosis was confirmed at operation in 13 cases, while the other 17 patients had abdominal pain and a high plasma amylase (>1000 Somogyi units/100 ml).

Hypocalcaemia (plasma calcium <8·9 mg/100 ml) was observed in 12 cases. Parathyroid hormone was assayed on 21 samples in 11 hypocalcaemic patients and on 13 samples in 3 normocalcaemic subjects. Plasma glucagon was measured in all these subjects. Plasma calcitonin was assayed on 6 samples in 2 of these hypocalcaemic cases and another hypocalcaemic patient. Plasma glucagon was also measured in 12 other normocalcaemic patients with pancreatitis. In 11 of these subjects plasma calcium and glucagon were measured before and 1 and 12 hours after giving glucagon (an initial bolus dose of 1 mg intravenously followed by a continuous intravenous infusion at 1–1½ mg 4-hourly).

Results

Parathyroid hormone was undetectable in the plasma of 8 patients with hypocalcaemia (calcium: range 6·7–8·8, mean 7·8 mg/100 ml). One patient with a plasma calcium of 8·5 mg/100 ml had an elevated parathyroid hormone level of 675 pg/ml, while 3 other subjects had plasma parathyroid hormone levels of 100–175 pg/ml. One of these subjects was hypocalcaemic (plasma calcium 8·5 mg/100 ml), while 2 were normocalcaemic (plasma calcium 9·0–9·9 mg/100 ml).

Serial changes in plasma parathyroid hormone were noted in 3 subjects. The first had a markedly elevated level of 1·5 ng/ml when the plasma calcium was 8·9 mg/100 ml. A second sample 24 hours later showed a marked fall in parathyroid hormone to 0·5 ng/ml and a fall in plasma calcium to 8·5 mg/100 ml. The second subject (*Fig.* 1) initially had a high plasma parathyroid hormone level and was normocalcaemic; plasma parathyroid hormone fell gradually but the

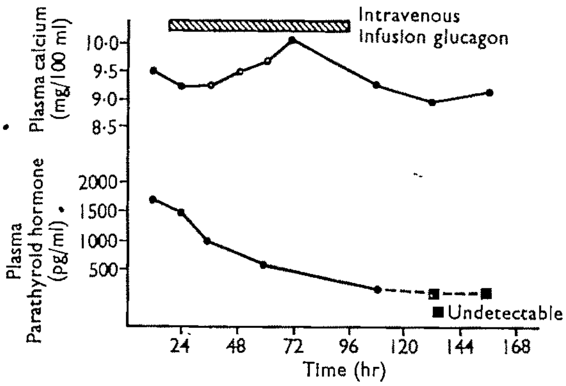

Fig. 1. Serial changes in plasma parathyroid hormone in a normocalcaemic subject.

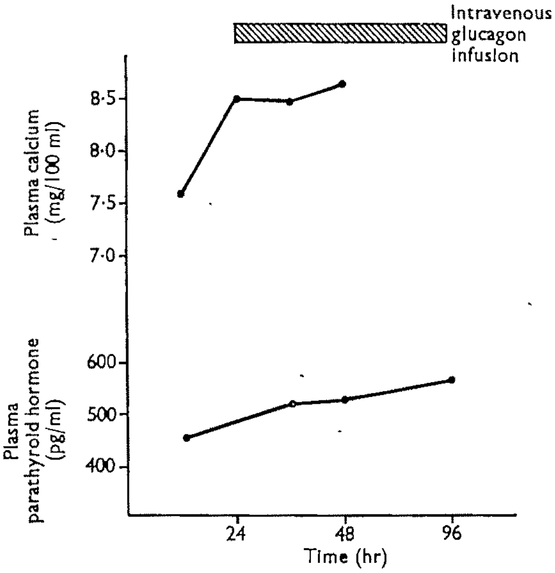

Fig. 2. Serial changes in plasma parathyroid hormone in a patient who was initially hypocalcaemic.

plasma calcium remained within normal limits. Glucagon infused intravenously did not result in hypocalcaemia. The third patient (*Fig.* 2) was initially hypocalcaemic, but later plasma parathyroid hormone and plasma calcium both rose; glucagon infusion was not associated with hypocalcaemia.

Calcitonin was undetectable in 6 plasma samples assayed in 3 hypocalcaemic patients (assay limit of detection, 500 pg/ml).

The mean fasting plasma glucagon level in 15 normal subjects was 0·48 (±0·08) ng/ml, and in 26 patients with acute pancreatitis 0·45 (±0·07) ng/ml. Following glucagon infusion, mean plasma glucagon rose significantly ($P < 0{\cdot}025$) at 1 hour by 3·4 to 4 ng/ml, except in 2 patients whose plasma glucagon rose from 0·25 to 0·33 ng/ml and fell from 0·63 to 0·54 ng/ml respectively. These 2 subjects showed a significant increase in plasma glucagon to 0·68 and 2·2 ng/ml respectively 12 hours after starting the glucagon infusion. There was no significant difference between plasma glucagon values at 1 and 12 hours following glucagon infusion. Plasma calcium showed no significant fall from 0 to 1 hour but fell significantly from 0 to 12 hours ($P < 0{\cdot}025$); the difference between plasma calcium at 1 and 12 hours was also significant ($P < 0{\cdot}025$). However, the correlation between the change in plasma glucagon with change in plasma calcium between 0 and 1 hour showed that the greater the increase in glucagon concentration the smaller was the fall in plasma calcium. At 12 hours there was no significant relationship between the fall in plasma calcium with change in plasma glucagon concentration either from the pre-infusion value or from the 1-hour value after the onset of glucagon infusion.

Discussion

Our findings indicate that persistent hypocalcaemia associated with acute pancreatitis is due to relative deficiency of parathyroid hormone and is unrelated to plasma glucagon and calcitonin levels. These conclusions are based on the fact that no parathyroid hormone was detectable in the plasma of 8 patients with hypocalcaemic acute pancreatitis. Furthermore, in 1 patient plasma parathyroid hormone fell from 1·5 to 0·5 ng/ml despite a fall in plasma calcium from 8·9 to 8·5 mg/100 ml, although one would have reasonably expected plasma parathyroid hormone to have risen in the presence of hypocalcaemia. On the other hand, plasma parathyroid hormone was detectable in a number of patients with normocalcaemic pancreatitis, indicating maintenance of normal plasma calcium levels by the action of parathyroid hormone on bone and kidney.

There is no doubt that serum levels of parathyroid hormone rise in patients with acute pancreatitis and this is well demonstrated in *Fig.* 1, which shows high levels of parathyroid hormone in a normocalcaemic patient. Normally, plasma parathyroid hormone levels rise in response to an acute fall in plasma calcium (Ramberg et al., 1967; Buckle, 1970), so that the patient whose hormone levels are represented in *Fig.* 1 must have had an initial fall in plasma calcium which triggered off increased secretion of parathyroid hormone. The resultant correction of plasma calcium by the actions of parathyroid hormone reduces further secretion of the hormone by the calcium feedback mechanism, blood levels of parathyroid hormone gradually falling to undetectable concentrations as demonstrated in our patient. The concept of an increasing parathyroid hormone concentration in response to hypocalcaemia in acute pancreatitis is supported by the findings in another patient (*Fig.* 2) in whom plasma parathyroid hormone levels gradually rose in association with a rising plasma calcium. Thus, although it is clear that plasma parathyroid hormone levels may rise in acute pancreatitis and correct any initial fall in plasma calcium, we have also shown that an elevated plasma concentration of parathyroid hormone is not a characteristic feature of patients with persistent hypocalcaemic acute pancreatitis, strongly suggesting the presence of a relative deficiency of parathyroid hormone in these patients.

Further evidence in support of the concept that persistent hypocalcaemia in acute pancreatitis is due to a deficiency of parathyroid hormone is provided by the findings of Hayes (1955) and Hernandez et al. (1961), who showed that intravenously administered parathyroid hormone corrected hypocalcaemia in patients with acute pancreatitis who had previously not responded to intravenous calcium therapy.

One possible explanation to account for the apparent parathyroid hormone deficiency in patients with acute hypocalcaemic pancreatitis is failure of the parathyroid glands to maintain secretion of the hormone. It is generally believed that the parathyroid glands store only small quantities of parathyroid hormone and it is possible that they become rapidly depleted of hormone in the presence of continued hypocalcaemic stress. Alternatively, there may be increased inactivation of circulating parathyroid hormone by proteolytic enzymes, and in support of this possibility is the fact that proteolysis of plasma proteins is known to occur following incubation with trypsin (Rocha e Silva et al., 1949).

We have also attempted to elucidate the role of the hormones glucagon and calcitonin in the pathogenesis of hypocalcaemia in acute pancreatitis. Elevated plasma glucagon has been reported in patients with pancreatitis and in dogs with experimental pancreatitis (Paloyan, Lawrence et al., 1966; Paloyan, Paloyan et al. 1966). Since glucagon induces a fall in plasma calcium it was suggested that hyperglucagonaemia might contribute to hypocalcaemia associated with acute pancreatitis (Paloyan et al., 1967; Cortes, 1971). A raised plasma glucagon might induce hypocalcaemia by direct action on bone (Stern and Bell, 1970) or by release of calcitonin from the thyroid gland (Care et al., 1970).

In dogs with experimental pancreatitis plasma glucagon levels first rise and later fall before the death of the animal (Knight et al., 1972). In patients with acute haemorrhagic pancreatitis plasma glucagon levels are low (Day et al., 1972), whereas in non-haemorrhagic acute pancreatitis plasma glucagon levels are not significantly different from those of normal fasting subjects. In all these experimental and clinical studies there is no correlation between changes in plasma calcium and glucagon levels. Furthermore, during intravenous infusion of glucagon in 11 of our patients there was no quantitative relationship between plasma calcium and glucagon concentrations despite marked rises in plasma levels of glucagon. Indeed, much larger doses of glucagon produce only mild hypocalcaemia in man, 2 mg given intravenously over a 5-minute period resulting in a fall in plasma calcium of 0·05 to 1 mg/100 ml (Condon, 1973).

We have studied one other possible contributory factor, namely calcitonin, a hormone which is released from the thyroid glands of animals by glucagon (Care et al., 1970).

No calcitonin was detectable by radio-immunoassay in the plasma of 3 patients with marked hypocalcaemia associated with pancreatitis. This does not exclude the possibility of elevated plasma calcitonin levels below the limit of detection of the assay (500 pg/ml). Elevated calcitonin levels are, however, unlikely to result in severe hypocalcaemia since a low plasma calcium is not a feature of patients with medullary cell carcinoma of the thyroid who have high plasma hormone levels (Cunliffe et al., 1968; Tubiana et al., 1968; Milhaud et al., 1969).

There has in the past been no general agreement as to the factors accounting for a fall in plasma calcium in acute pancreatitis. The calcium soap theory appears an inadequate explanation since serum calcium often remains unchanged despite administration of intravenous calcium in doses equal to or greater than the amount of calcium calculated to be bound to the necrotic fatty tissue of patients with acute hypocalcaemic pancreatitis. Even if plasma glucagon and calcitonin concentrations were to increase for a short period of time during the development of acute pancreatitis only a small fall in plasma calcium is to be expected, since in the presence of normal parathyroid gland function serum calcium is rapidly restored to normal. We, therefore, propose that there is an immediate fall in plasma calcium in acute pancreatitis due to precipitation of calcium in areas of fat necrosis and less probably an elevation of both plasma glucagon and calcitonin concentration for a short period of time. Plasma calcium is rapidly restored to normal by increased secretion of parathyroid hormone, but in patients with persistent hypocalcaemic pancreatitis, plasma parathyroid hormone fails to rise because of either decreased secretion or increased proteolytic degradation of the hormone. If this interpretation of our findings is correct parathyroid hormone may be of therapeutic use in patients with acute pancreatitis who have persistent hypocalcaemia which is resistant to calcium therapy; likewise the vitamin D metabolite 25-hydroxy-colecalciferol may also be of benefit in this condition.

An appraisal of peritoneal lavage in the diagnosis of the acute abdomen

CHRISTINE EVANS, A. RASHID, I. L. ROSENBERG
AND A. V. POLLOCK*

SUMMARY

Forty-seven selected patients presenting with acute abdominal symptoms were investigated by examination of the fluid obtained by peritoneal lavage. In 34 patients this confirmed the clinical diagnosis, in 11 it was a more positive help in that it corrected an erroneous clinical diagnosis and in 2 the results of the investigation were misleading.

In the diagnosis of acute abdominal emergencies the experienced clinician achieves an accuracy of almost 80 per cent. With the help of a computer programed to accept important aspects of history and physical signs, this approaches 92 per cent (de Dombal et al., 1972). There are certain situations, however, in which it is difficult to make a confident diagnosis. These often arise because of poor cooperation from the patient due to age, low intelligence, altered consciousness or the presence of severe injuries elsewhere. It is for these patients that examination of the peritoneal fluid can be a valuable adjunct to familiar radiological and laboratory investigations. We favour peritoneal lavage, as it is often impossible to obtain fluid by mere paracentesis.

Materials and methods

Peritoneal lavage was not a routine examination for all patients with acute abdominal symptoms, but 47 were selected for lavage in whom a confident diagnosis could not be made after routine investigations. Abdominal puncture has been avoided in patients with considerable bowel distension or multiple scars which could indicate widespread adhesions.

The patient was usually tranquillized by an intravenous injection of diazepam 10 mg, and the abdominal wall infiltrated with 2 per cent lignocaine. A Dialaflex Mark II dialysis catheter (Allen & Hanburys Ltd, London) was introduced into the peritoneal cavity (usually in the midline below the umbilicus, but avoiding any previous laparotomy scar) and 1 litre of saline or other sterile fluid was run in within 5–10 minutes. The fluid was allowed to remain for 10 minutes, and the patient encouraged to move about if his general condition allowed. The fluid was then drained and after removal of the catheter the skin was closed with a single suture.

We have tried the 'two-needle' modification of the technique published by Civetta et al. (1970), but found it less reliable than the method described here.

Aliquots were taken into sterile containers for bacteriological and biochemical investigations. The most important tests were an examination of a Gram-stained centrifuged deposit for cells and organisms and estimation of the amylase content. The fluid was cultured, but the delay entailed made this of relatively little importance.

Normal fluid contained less than 0·1 × 10^{12} red cells/litre, an occasional polymorph and no organisms; it was sterile, with less than 100 Somogyi units of amylase/100 ml.

Results

Forty-seven patients were selected for this investigation on account of diagnostic difficulty (*Table I*). In 34 the tentative clinical diagnosis was confirmed by the results of examination of the peritoneal fluid, and the final diagnosis agreed with both. Estimation of the amylase content of the fluid was unhelpful. The highest level (3600 u./100 ml) was found in a patient with traumatic rupture of the ileum, and 2 of the 7 patients with acute pancreatitis had less than 100 u./100 ml in the peritoneal fluid.

In contrast with these merely confirmatory results, there were 11 patients in whom the provisional diagnosis was shown to be erroneous by peritoneal lavage, which was therefore of great value (*Table II*).

On the other hand, in 2 patients the returned fluid was normal but serious disease was present. In the first an abdominal X-ray subsequently showed a small amount of air under the right dome of the diaphragm, and the presumed small perforation of a duodenal ulcer was treated conservatively with success. In the second, delayed rupture of the spleen necessitated splenectomy 24 hours after lavage had produced normal fluid. These were the only misleading results.

It must be stressed that lavage can only diagnose the presence or absence of intraperitoneal bleeding or inflammation, and not the cause.

In no patient was any untoward reaction detected, nor was bowel perforated by a dialysis catheter, although we accept that this risk exists (Thal and Shires, 1973). On the contrary, many patients volunteered that they felt better as a result of the 'treatment'.

Discussion

Diagnostic abdominal paracentesis was first reported by Salomon (1906), who described catheterization of the peritoneal cavity through a cannula, with

Non-specific abdominal pain	7	7	0	0	0	6	0	1
Total	47	12	18	31	4	28	11	8

Table II: DETAILS OF 11 PATIENTS IN WHOM PERITONEAL LAVAGE CORRECTLY CONTRADICTED THE PROVISIONAL DIAGNOSIS

Provisional diagnosis	Lavage fluid findings	Final diagnosis	Procedure
Acute cholecystitis	Normal	Bronchopneumonia	No laparotomy
Acute appendicitis	Normal	Non-specific abdominal pain	Negative laparotomy
Peritonitis	Normal	Partial intestinal obstruction	Later laparotomy
Peritonitis	Normal	Urinary tract infection	No laparotomy
Acute cholecystitis	Normal	Carcinoma, transverse colon	Subsequent resection
Peritonitis	Normal	Urinary tract infection	No laparotomy
Peritonitis	Normal	Gallstone colic	No laparotomy
Acute cholecystitis	Normal	Cardiac infarct	No laparotomy
Non-specific abdominal pain	Pus cells Amylase 105	Pancreatic abscess	Laparotomy and drainage
Pancreatitis	*Escherichia coli* Pus cells No amylase	Perforated appendix	Laparotomy and appendicectomy
Bile peritonitis after cholecystectomy	Blood	Haemoperitoneum	No laparotomy

aspiration of fluid for microscopic examination. The method did not become popular, possibly because of Salomon's warning of the dangers of actually causing peritonitis.

It has been resuscitated sporadically, but its value is lessened by the frequent failure to obtain fluid. Four-quadrant (Baker et al., 1967) or pelvic (Gjessing et al., 1972) aspiration has been advocated, but in the presence of localized intraperitoneal inflammatory disease (as opposed to general peritonitis) fluid is unobtainable by any method in 90 per cent of cases (Baker et al., 1967; 'a negative paracentesis has no positive significance').

Root et al. (1965) introduced a refinement of diagnostic paracentesis for the investigation of intra-abdominal injuries due to non-penetrating trauma. Through a dialysis catheter they ran in a litre of fluid and then aspirated it. They were, however, more interested in the haemoglobin content of the returned fluid than in the presence of pus cells.

Subsequent publications have extended the indications for diagnostic peritoneal lavage (as opposed to simple paracentesis) (Veith et al., 1967; Thal and Shires, 1973) and it is now recognized as a useful aid in the diagnosis of the presence of intra-abdominal injury or inflammation.

Regrettably the amylase content of the lavage fluid has not helped in the diagnosis of acute pancreatitis. It was normal in 2 out of the 7 cases, and raised in 7 patients with other forms of peritonitis.

Abdominal lavage in blunt trauma

WILLIAM GILL, HOWARD R. CHAMPION, WILLIAM B. LONG,
JOSEPH JAMARIS AND R. ADAMS COWLEY*

SUMMARY

A technique for abdominal lavage is described and was used to evaluate the abdomen of 671 multiple trauma victims. In 44 per cent (299 cases) there was a bloodstained return and these were regarded as positive. Patients with a positive result underwent exploratory laparotomy which revealed that 89 per cent had significant intra-abdominal trauma requiring a surgical procedure, 8 per cent had trauma which did not require any active surgical correction and 3 per cent had no abnormal findings. Of all the lavages performed, there were 0·11 per cent false positive and 0·03 per cent false negative results. The value of the test in the context of multiple trauma is emphasized.

THE mortality rate in victims of blunt abdominal trauma remains unnecessarily high (Aho and Rasturia, 1971), partly as a result of the perpetuation of inappropriate medical teaching. The classic diagnostic approach of a clinical history proceeding to inspection, percussion, auscultation and palpation followed by special investigations has become almost obsolete in the evaluation of an abdomen in a multiple trauma patient.

Needle abdominal paracentesis described by Neuhof and Cohen in 1926, while clearly a diagnostic advance, was associated with a high number of false negative results (Fitzgerald et al., 1960; Giacobine and Siler, 1960). The introduction of four-quadrant 'tapping' reduced the frequency of false negatives but did not eliminate them (Olsen and Hildreth, 1971). In 1965 Root et al. discussed abdominal lavage as a further diagnostic advance in abdominal trauma, but the technique failed to gain wide acceptance by those dealing with trauma victims.

A slight modification of the technique of Root et al. (1965) has been employed in the Maryland Institute for Emergency Medicine during the past 2 years and the experience gained is described.

Technique of abdominal lavage

1. The bladder is emptied by Foley catheterization.
2. A nasogastric tube is inserted to empty the stomach.
3. A 5 × 7·5 cm area of skin in the midline below the umbilicus is prepared with Betadine solution and draped.
4. One per cent Xylocaine (and adrenaline) is used to infiltrate the midline for approximately 3 cm below the umbilicus and down to the peritoneum.
5. A midline subumbilical incision through skin and subcutaneous tissue is made for 2–4 cm depending on the patient's obesity.
6. Meticulous haemostasis is mandatory and is aided by the adrenaline.
7. The preperitoneal space is entered through the linea alba. If the inferior rectus sheath is entered erroneously the muscle is deflected laterally and an entrance made through the posterior sheath. Improved visualization is obtained by grasping the cut edges of the posterior rectus sheath or linea alba and pulling upwards.
8. The peritoneum is exposed, grasped and tented with two Kelly clamps.
9. After ensuring that no adherent bowel is included in the clamps, a peritoneal purse string suture is placed around the Kelly clamps.
10. A 2–3-mm incision is made in the peritoneum.
11. A standard peritoneal dialysis catheter without the trocar is inserted through this incision into the peritoneal cavity and the purse string suture immediately tightened.
12. The catheter is gently aspirated and an obvious return of blood would obviate further evaluation.
13. If no bloodstained fluid is aspirated, 1000 ml of sterile isotonic crystalloid solution are infused through the catheter by a routine intravenous infusion set. When the intraperitoneal infusion is complete the empty bottle is placed on the floor and the lavage fluid allowed to refill the bottle by gravity.
14. During the infusion the patient should be in a slight Trendelenburg position which is reversed when the infusate is returning to the bottle.
15. The wound is packed with gauze if surgery is to follow or sutured if the result is negative.

Patients

All admissions to the Maryland Institute for Emergency Medicine for the year 1973 were included in the study. During the first 6 months abdominal lavage was performed only for specific indications. Over the latter 6 months the examination was performed on all patients with blunt trauma. The technique described above was rigidly adhered to, and children were lavaged with 500 ml and adults with 1000 ml of crystalloid solution. Penetrating abdominal trauma was excluded from the study because of a different approach to this problem.

When poor technique was recognized as a possible cause of a very faint discoloration in the returning fluid, a second litre of crystalloid solution was infused. Persisting or increasing discoloration in the return from the second bottle was required before the result

False negative	2	0·03

was regarded as positive. When poor return of the fluid from the abdominal cavity occurred despite gentle adjustment of the catheter a second litre was also infused.

All patients with bloodstaining of the lavage return were subjected to laparotomy. The intraperitoneal findings were classified as clinically significant when surgical correction or drainage was required, and clinically insignificant when the abnormal findings required no active therapy. A negative laparotomy indicates the total absence of traumatic intraperitoneal pathology and identifies a false positive result.

An analysis was made of some of the factors likely to confuse a clinical attempt to evaluate the abdomen, and related specifically to associated central nervous system and thoracic trauma and the presence of alcohol in the blood.

No attempt was made to correlate the clinical findings with the lavage results and eventual pathology or to correlate the degree of staining of the lavage return with the intra-abdominal pathology, as described by Olsen et al. (1972).

Results

In the 12-month period studied, 943 patients were admitted to the Maryland Institute for Emergency Medicine of which 831 (88 per cent) were trauma victims transferred directly from the scene of the accident or from another hospital. Six hundred and forty-one (68 per cent) of these admissions arrived by helicopter. Abdominal lavage was performed in 671 patients to exclude traumatic intraperitoneal pathology. Three hundred and seventy-two (55·23 per cent) were found to be negative and 299 (44·52 per cent) positive (*Table I*). The latter 299 patients were subjected to exploratory laparotomy. In 266 (89 per cent) there were surgically significant lesions, and 8 (3 per cent) were negative (*Table II*). The clinically significant findings are listed in *Table III*. Twenty-five (8 per cent) patients had clinically insignificant findings at laparotomy. False negatives occurred in 2 instances (*Table IV*).

Of the 831 trauma admissions, 50 per cent showed alcohol in their blood on arrival and 25 per cent had over 0·15 mg/100 ml (the upper legal limit for driving in Maryland). Three hundred and forty-nine patients sustained central nervous system (CNS) injury with impaired consciousness, and 132 (38 per cent) of these required laparotomy for abdominal trauma. Almost half (44 per cent) of the patients with abdominal injury had a CNS injury. Two hundred and twenty-one patients sustained a thoracic injury and 124 were submitted to exploratory laparotomy. Thoracic trauma was present in 41 per cent of patients with abdominal injury, and 56 per cent of all the patients with thoracic injury underwent laparotomy. Multiple trauma involving the thorax, central nervous system and abdomen occurred in 50 patients; only 38 patients had isolated abdominal trauma, and 65 per cent of all the trauma patients had one or more fractures.

Discussion

Mortality from abdominal trauma is related not only to the severity of the injury and associated trauma but also to delay in diagnosis (Williams and Zollinger, 1959; McLeod and Brown, 1966; Bolton et al., 1973). The difficulties of clinical diagnosis in the presence of head injury, alcoholic intoxication (Williams and Zollinger, 1959; Nicholson and Golden, 1966) and extra-abdominal trauma (Macbeth, 1966; Olsen and Hildreth, 1971) are well described.

In the Institute's special admitting areas, abdominal evaluation is limited to abdominal lavage after a cursory inspection for visible expansion. Radiological examination of the abdomen is not performed routinely and haemodynamic stabilization of the patient is clearly a priority. Because abdominal lavage is a routine part of our initial resuscitative and diagnostic effort, the mortality and morbidity related to delay in diagnosis are effectively removed. Meticulous technique in the performance of the lavage is essential for accuracy, and visceral damage is avoided by elevating the peritoneum before making the incision. A crystal-clear return of lavage fluid is the only confirmation of a technically perfect lavage, and bloodstaining of the fluid means that blood from the incision has entered the peritoneal cavity during the catheter insertion or that intraperitoneal bleeding is present. Poor technique accounted for all our false positive results.

Twenty-five (8 per cent) of our patients had exploratory laparotomy findings not requiring any further surgical procedure. Twenty of these had mildly positive lavage results, although the remainder showed deeper staining of the effluent.

Various attempts to increase the accuracy of abdominal lavage include gradations based on red and white blood cell counts in the fluid, amylase estimations (Perry and Strak, 1972) and the presence of ammonia (Mansberger et al., 1959) to mention a few. We have found such scales to be too time-consuming in an emergency situation and to provide no useful additional information. Very weakly bloodstained lavage fluid not infrequently indicates a bowel perforation with minimal bleeding from the edges of the hole or may be the only clue to a ruptured duodenum or other retroperitoneal injury. It is for this reason that all bloodstained lavage results are regarded as an indication for exploratory laparotomy. In this context the deliberate acceptance of a number of exploratory laparotomies revealing 'clinically insignificant' pathology is necessary just as the negative laparotomy is acceptable in other situations when it is used as the final diagnostic manœuvre. If anything, its use in the management of trauma is more essential because of the detrimental effect of delay in treatment.

Constructive attention should be directed towards the false negative results obtained rather than the false positives because it is in these patients that a delay in diagnosis is likely to increase the mortality and morbidity. It is possible that previous surgery in the abdomen may result in the isolation of an injured viscus by fibrous adhesions and prevent adequate distribution of the instilled crystalloid solution. The presence of healed abdominal scars should consequently stimulate the surgeon to consider an alternative site for the lavage incision, and to agitate or promote movement of the abdomen to ensure good circulation of the fluid. The surgeon must also be wary of the potential danger of bowel perforation during the intraperitoneal introduction of the catheter.

Trauma confined to the retroperitoneal space can never be excluded with certainty by abdominal lavage (Olsen and Hildreth, 1971), but to date this has not been a problem in our patient population. This may be related to the fact that the magnitude of trauma required to injure retroperitoneal structures produces associated intraperitoneal trauma which is detected by the lavage. In our experience, retroperitoneal hematomas almost always stain the lavage fluid even though covered by intact peritoneum.

The 2 false negative results reported were patients in whom rupture of the left hemidiaphragm was apparent on chest X-ray, with translocation of the stomach, colon and spleen into the chest. Both underwent laparotomy despite negative lavages, and in both instances splenic rupture was present. In one patient 500 ml of blood were found in the thoracic cavity without spillage into the abdominal cavity—a presumed result of the herniation and negative intrathoracic pressure. The ruptured diaphragm thus presents a further weak area for lavage diagnosis, though it is unlikely to occur unless there has been a major disruptive force and other visceral injury, or to escape detection on chest X-rays.

Abdominal lavage is still confused with abdominal 'taps' in the minds of many surgeons despite the ever increasing reports in the literature clarifying the procedure. Mis-statements in medical texts are numerous and reflect the inadequate experience of the authors in many cases. It has been stated that as little as 200 ml of blood in the peritoneal cavity may be detected by lavage when quite clearly a few drops of blood introduced at the time of incision will give a false positive result.

At present, we rely almost entirely on this procedure for our initial evaluation of the abdomen in blunt trauma victims and have had no cause for regret. We feel that knowledge of the value of this tool is lost in the midst of long descriptions of how to examine and assess the abdomen in this type of patient and that current texts have not yet fully appreciated the real value or import of the test. The time is overdue for change however much it saddens the traditional diagnostician's heart.

Extrinsic duodenal obstruction in infants and children

G. TRYFONAS AND D. G. YOUNG*

SUMMARY

A series of 34 patients with extrinsic duodenal obstruction is described. The diagnosis and treatment are discussed. Five infants died and the findings are given. The remaining 29 have progressed normally.

DUODENAL obstruction in a newborn infant was first described by Calder (1733), and Ernst (1916) was the first to report its successful treatment. Subsequently, it became apparent that there were two types of neonatal duodenal obstruction. The cause of intrinsic duodenal obstruction (atresia, membrane or severe stenosis) was clearly defined in the nineteenth century, but the cause of extrinsic duodenal obstruction due to Ladd's bands or volvulus of the midgut was first described by Dott (1923). Extrinsic duodenal obstruction may also occur in later infancy and childhood because of compression of the third portion of the duodenum by the superior mesenteric artery.

Higgins (1923) first reported a successful operation on an infant with extrinsic duodenal obstruction. The operative approach described by Ladd (1937) has become generally accepted as the best treatment at any age for extrinsic duodenal obstruction (Louw, 1960). Details of series of patients with extrinsic duodenal obstruction are remarkably scanty, with the main report coming from Boston (Gross, 1953) and another from London (Young and Wilkinson, 1966). A study of 34 infants and children with extrinsic duodenal obstruction is presented here.

Patients

The case records of 34 infants and children presenting with signs or symptoms which were proved to be due to extrinsic duodenal obstruction and who were admitted to the surgical wards at the Royal Hospital for Sick Children, Glasgow, between 1966 and 1973 have been reviewed.

Age and sex

On admission the ages of the patients varied from 1 day to 11 years. Twenty-eight were admitted in the neonatal period and the mean age on admission was 6·8 days. The remaining patients were admitted at the age of 5 months, 7 months, 2, 3, 5 and 11 years. There was an equal sex distribution.

Pregnancy and birth weight

In none of the 31 pregnancies of which details were known had hydramnios occurred. Two infants were born before the 36th week. One infant had a birth weight of 1·56 kg and the remainder weighed from 2·5 to 4·5 kg.

Clinical features

All the neonates showed signs of an upper intestinal obstruction. All the patients had vomited bile-stained fluid. The vomiting did not always continue. In some it subsided and returned only weeks or months later. In 2 patients bile-stained vomiting had been episodic over years and this had given rise to difficulty in making a diagnosis. Only 2 infants failed to pass meconium and most had passed changed stools. In the older infants and children bowel habit had been normal until the acute episode, except in 1 child who had been constipated until the age of 3 years. He then had an acute episode of severe abdominal pain and bile-stained vomiting.

Diagnosis

Bile-stained vomiting should always arouse the suspicion of intestinal obstruction, but in the neonatal period there are other causes of bile-stained vomiting. Unlike intrinsic duodenal obstruction, X-rays of the abdomen in the erect posture were not always helpful in making the diagnosis of extrinsic duodenal obstruction. An abnormal but variable pattern of gas distribution throughout the gut with fluid levels in the stomach, and sometimes in the duodenum and the small bowel when volvulus had occurred, were the most common findings; lack of the normal distribution of gas throughout the gut of an infant is also significant (*Fig.* 1). As the obstruction of the duodenum is acute, proximal dilatation of the duodenum is not marked and so the 'double bubble' sign found in the longer standing intrinsic obstruction may not be seen. When straight X-rays did not clarify the position radiological studies using a contrast medium (e.g. barium sulphate or Gastrografin) were made to define the anatomical arrangement. This was given orally (*Fig.* 2) or instilled into the large bowel.

In the infants or children with malrotation the duodenojejunal flexure was displaced to the right and the proximal small bowel was lying predominantly on the right side of the peritoneal cavity rather than on the left. Follow-through studies demonstrated the abnormal position of the proximal large bowel (*Fig.* 3). Barium enema examination was used on occasion to define the malrotation of the bowel. Rather than a barium enema, the technique recommended by Rickham (1969) of filling the large bowel with air can delineate the large bowel and caecum. The normal position of the large bowel does not exclude extrinsic duodenal obstruction, and 2 neonates with volvulus of the small bowel with a normally rotated colon were treated.

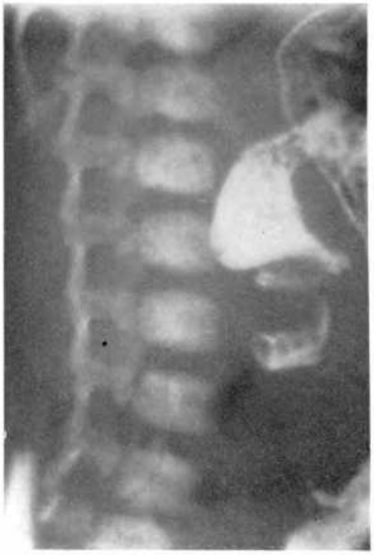

Fig. 2. Barium meal film showing a dilated duodenum which is constricted in the lower part due to extrinsic pressure from bands. Note: There is not the gross proximal dilatation seen with intrinsic obstruction.

Pathological anatomy

Extrinsic duodenal obstruction usually falls into one of three groups, but a mass compressing the duodenum can cause obstruction. During the period under review no such patient was admitted.

Type A. Malrotation with bands

The term 'malrotation' is widely used when the midgut does not complete the normal process of

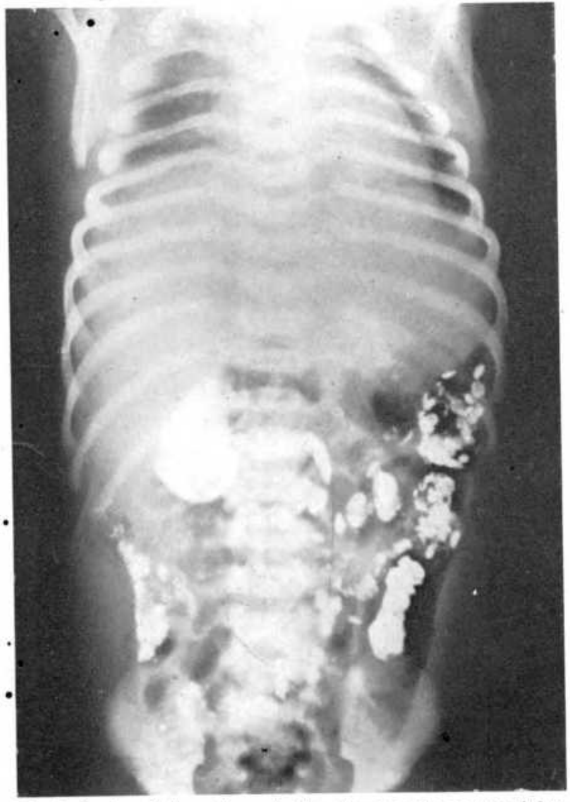

Fig. 3. Barium follow-through film showing the caecum lying in the midline.

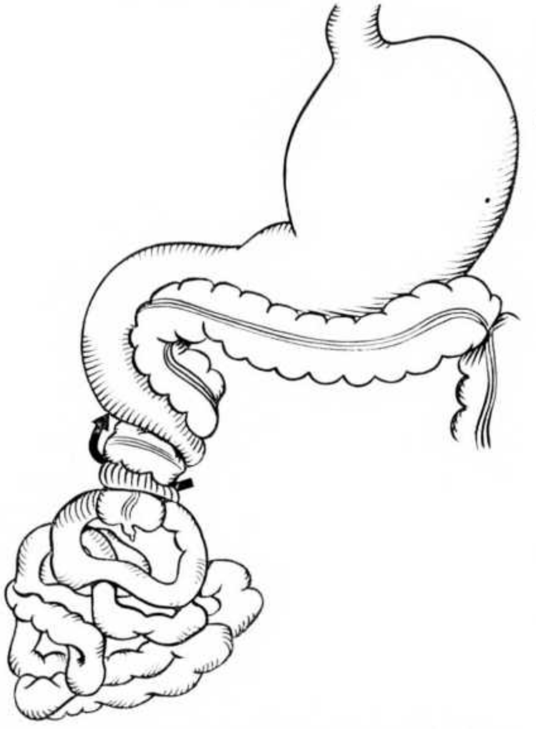

Fig. 5. Diagrammatic representation of malrotation with volvulus.

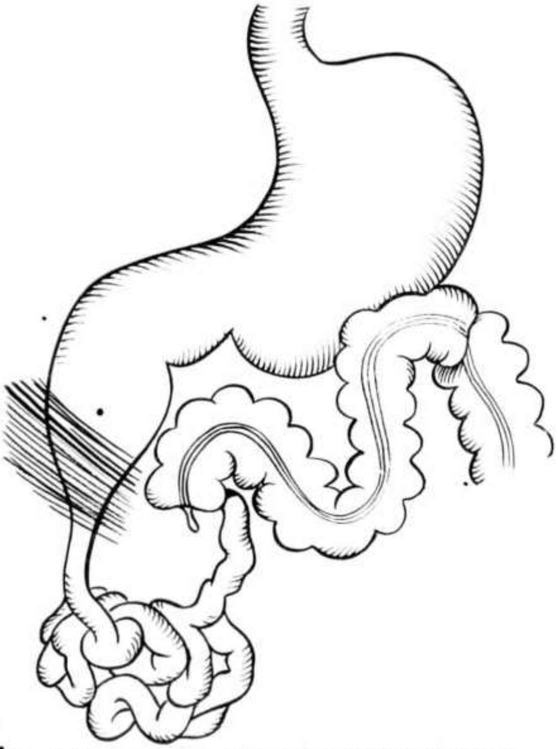

Fig. 4. Diagrammatic representation of malrotation with Ladd's bands obstructing the duodenum.

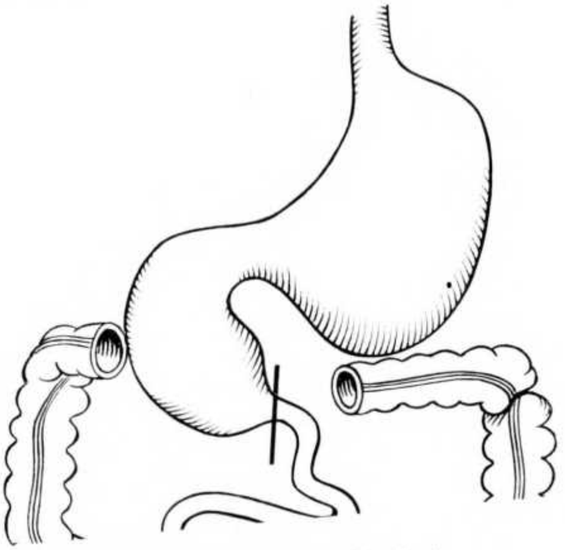

Fig. 6. Diagrammatic representation of duodenal obstruction due to superior mesenteric vessels.

rotation and fixation in utero. With this incomplete rotation the duodenum fails to cross the midline to the normal duodenojejunal junction at the ligament of Treitz. The caecum fails to rotate across the midline and down into the right iliac fossa, and from the caecum peritoneal 'bands' spread to the posterior abdominal wall and sometimes to the gallbladder and undersurface of the liver. These bands cross the duodenum and in 17 patients in the present series were the cause of the obstruction (*Fig.* 4). The obstruction usually began a few days after birth when the colon becomes more active. The bands are pulled across the descending duodenum distal to the entrance of the bile ducts.

Type B. Malrotation with volvulus of the midgut

With incomplete rotation of the gut the base of the mesentery is narrow. This allows the midgut loop to twist upon itself (*Fig.* 5). Thirteen patients in the present series had volvulus of the midgut loop, and a further 2 had complete rotation of the large bowel but incomplete rotation of the duodenum and had volvulus of the proximal part of the midgut loop. This type of obstruction was mentioned by Wilkinson (1973). When volvulus supervenes the mesenteric vessels may be obstructed and cause infarction of the bowel. Two infants in the present series had extensive gangrene of the bowel and a third had incipient gangrene with the bowel about to perforate at the time laparotomy was performed.

Type C. Superior mesenteric artery obstruction, also referred to as 'duodenal ileus'

This third type of obstructing lesion of the duodenum is uncommon and occurred in 2 infants in this series (*Fig.* 6). The duodenum passes behind the superior mesenteric vessels which press on the duodenum and may cause obstruction which is always incomplete. The patients may adopt unusual postures, particularly after meals, to relieve the pressure of the mesenteric vessels on the duodenum. This apparently bizarre behaviour may lead one to suspect psychiatric disease, but the relief of the obstruction by postural alteration can be demonstrated at radiological screening.

Treatment

The operative correction in all the patients of this series (including the 2 with obstruction due to the superior mesenteric vessels) was basically the procedure described by Ladd (1937). The abdomen was usually opened through a transverse incision and the peritoneal cavity explored. The caecum and proximal colon were then mobilized by dividing the bands extending from these organs. The large bowel was displaced to the left side of the abdomen and in doing so the base of the mesentery was gradually broadened. Any rotation of the duodenum towards the left was undone so that the duodenum ran down the right paravertebral gutter into the proximal jejunum on the right. Fluids were usually administered by intravenous infusion for 48 hours after operation, when oral feeding was started. The appendix was removed from 12 of the patients in this series. Where volvulus had been present or when there was any doubt about the viability of the bowel, additional procedures such as appendicectomy were avoided.

Results

Five patients died, 1 just after admission and 4 during the first 24 hours after operation. Necropsies were permitted in 4 of the 5 patients who died. In 2 no precise cause of death was found. An unusual incidental finding in one of these was pneumatosis of the bladder. Bacteriological culture was negative and the lack of an inflammatory reaction in the submucosa of the bladder was against this being of infective origin.

In 1 infant mucopurulent material was present in the bronchi, the bronchopneumonia contributing to the fatal outcome, but it was felt that aspiration of a small quantity of vomit was the primary cause of the death. In another infant death was due to widespread staphylococcal infection. Two patients had gangrene of the bowel. The infant whose parents refused necropsy weighed only 1·56 kg and suffered from repeated apnoeic attacks following operation. It was presumed that death was the result of an apnoeic attack.

Discussion

The factors which interrupt the normal rotation of the gut remain obscure. In only one of the present series was a clear aetiological factor present. This baby was admitted on the first day of life with a left diaphragmatic hernia. Operation was carried out to repair the hernia but 1 week after the operation he started to vomit bile-stained fluid. A laparotomy was carried out and Ladd's (1937) procedure was performed to correct the malrotation of the gut with bands which crossed the junction of the second and third parts of the duodenum.

A low incidence of associated abnormalities has been reported (Young and Wilkinson, 1968). In the present series, apart from the diaphragmatic hernia, there was no other serious congenital malformation but 1 infant was small and premature. Aitken (1966) has stressed the frequency of malrotation complicating intrinsic duodenal obstruction. All patients with intrinsic duodenal obstruction and malrotation have been excluded as the former was the primary cause of obstruction. The lack of patients with anomalies such as exomphalos or diaphragmatic hernia could be due to the latter conditions being treated within a few hours of birth. In both conditions laparotomy is usually performed and if duodenal bands likely to cause obstruction are present, these are divided. It has not been the author's experience to find potentially obstructive bands with these malformations.

Diagnosis of extrinsic duodenal obstruction depends on being aware of it as a possibility. When an infant has been feeding and then suddenly develops bile-stained vomiting an organic cause for this should be sought. Speed is essential as there is no external evidence to indicate which infants have volvulus (type B). This complication requires immediate correction as delay may result in gangrene of the small bowel. In 1 of the 15 type B cases the bowel was on the point of perforating at the time of laparotomy and delay for a few hours would have resulted in faecal peritonitis, and in 2 cases gangrene had supervened and both these patients died. Types A and C obstruction do not require urgent operation. It is

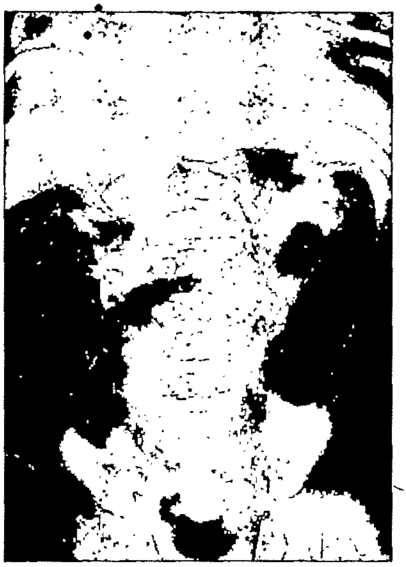

Fig. 7. Straight X-ray showing the small bowel on the right and large bowel on the left. Malrotation was confirmed subsequently at laparotomy for other reasons but the infant never had any signs of obstruction.

impossible in some cases to define whether the infant has type A or B obstruction from clinical or simple radiological investigations and these infants require urgent attention to prevent the bowel becoming gangrenous. Radiological evidence of extrinsic obstruction has already been shown to be variable. The danger is that the straight X-ray may not show any dramatic evidence of the duodenal obstruction and the diagnosis is missed. It must also be remembered that a contrast enema does not exclude volvulus of the small bowel which occasionally causes extrinsic duodenal obstruction. Radiological examination may show malrotation (*Fig.* 7), but the child may not require any active treatment. Warkany (1971) stated that 50 per cent of patients with malrotation do not require operation. All the patients in the present series were considered to require operation as they presented with signs of extrinsic duodenal obstruction.

The intermittent nature of duodenal obstruction of types A and C in some patients also causes difficulty in diagnosis. In the older boy with type C obstruction the bizarre positions that he adopted to relieve his obstruction and the periodic nature of the vomiting gave rise to the question of psychiatric disease. The same error has occurred in adults with this disorder. Diagnosis can be made only by barium meal examination. Louw (1960) indicated the improved results of the Ladd (1937) approach to the superior mesenteric artery obstruction. Other operations such as gastro- or duodenojejunostomy have only 'cured' about 2 of every 3 patients with this type of obstruction.

The danger of even a very small vomit or regurgitation in an infant cannot be overstressed and close immediate postoperative care is essential to prevent avoidable mortality. A significant fact was that all the infants, except the small premature baby, died during the night. In 2 if not 3 of the deaths it was felt that continuous supervision with immediate availability of experienced help, as is now routine, would have prevented the deaths. Unlike intrinsic duodenal obstruction, where there is a high mortality due to associated abnormalities, the extrinsic duodenal obstruction is usually an isolated defect.

Acknowledgments

We wish to thank the surgeons at the Royal Hospital for Sick Children, Glasgow, for permission to review their patients, and the nursing staff of the hospitals at which we have treated these infants for their care and attention.

Carcinoma of the pancreas and periampullary region: a clinical study in a district general hospital

D. J. T. WEBSTER*

SUMMARY

One hundred patients with pancreatic and periampullary carcinoma have been reviewed. Diabetes mellitus may be an early presentation. Painless jaundice has a relatively good prognosis. Fifteen patients have had curative procedures with a 31 per cent operative mortality. Mortality is influenced by age and serum bilirubin levels. Where palliative procedures are undertaken, this should include biliary diversion and gastro-enterostomy.

CARCINOMA of the head of the pancreas accounts for about 2500 deaths per year in England and Wales (Registrar General, 1971). The death rate seems to be increasing (Krain, 1970). No aetiological factor has been determined, although Wynder et al. (1973) have recently reported an attractive concept related to carcinogen excretion in the bile.

Most papers in the past have come from large centres with a special interest in the problem of pancreatic cancer. The figures from these series are therefore not representative of the disease as it affects the general population. This review was undertaken to assess the influence of treatment on the course of the disease in a district general hospital and in particular to define the place of radical surgery. Carcinomas of the ampulla and distal part of the bile duct have been included because even at operation it may be difficult to distinguish between them and carcinomas of the head of the pancreas.

Patients and methods

A diagnostic index recorded 108 patients as having pancreatic, bile duct or ampullary carcinoma between 1 January 1958 and 31 December 1972. Tumours of the upper biliary tree and gallbladder have been excluded.

Eight patients were excluded from this study, 5 because there was insufficient documentation and 3 because the diagnosis was subsequently revised on the basis of histological examination to hepatocellular carcinoma, benign cystadenoma of the pancreas and chronic pancreatitis respectively.

Operative death is defined as occurring within 1 month of operation or before discharge from hospital.

The sites of origin of the carcinoma are shown in *Table I.* The mean age of these patients was 63 years with an age range of 35–87. There were 52 men and 48 women.

On the basis of surgical management, the patients have been divided into three groups (*Table II*): 'radical' surgery is defined as excision of the tumour with a view to cure; 'palliative' surgery refers to bypass procedures of the biliary and/or gastro-intestinal tracts; the 'no treatment' group had either an exploratory laparotomy only or no operation at all. None of the patients was treated by radiotherapy or chemotherapy.

Table I: SITES OF ORIGIN OF CARCINOMA

Diagnosis	No. of cases	
Carcinoma of head of pancreas	75	92
Carcinoma of body and tail of pancreas	17

Mass	1	1
Psychosis	0	1

* Number with this symptom as first or leading complaint.
† Total number in the series with this symptom.

Findings

Presenting symptoms

The presenting symptoms are shown in *Table III.* Painless jaundice occurred in 38 patients and 11 of these had a radical procedure. In the remaining 27 patients 17 had definite evidence of unresectability. In 10 patients no assessment was recorded and a palliative procedure was performed.

The average duration of symptoms before operation is shown in *Table II.* There was no difference between the patients having radical or palliative procedures. The no treatment group had symptoms for twice as long before seeking medical advice. Patients with tumours of the body and tail of the pancreas had symptoms for longer (mean 8 months) compared with those with carcinoma of the head (mean 3 months). They more frequently fall into the no treatment group because of the position of the tumour.

---

* St Woolos' Hospital, Newport, Monmouthshire.
Present address: University Department of Surgery, Welsh National School of Medicine, Heath Park, Cardiff CF4 4XN.

Associated diseases

The associated diseases are shown in *Table IV*. Fifteen patients were found to have diabetes mellitus either at presentation or up to 8 years previously. Glucose tolerance tests were not performed routinely. Six patients had had diabetes mellitus for more than 3 years and 4 of these had become unstable shortly before symptoms of carcinoma appeared. There is no significant correlation between the site of the carcinoma and the occurrence of diabetes. Diabetes mellitus occurred in 17 per cent of head lesions and 20 per cent of body/tail lesions.

Cholelithiasis occurred in 14 patients. Six of these patients had had cholecystectomies from 2 to 20 years previously. In the other 8 patients the stones were incidental findings at the time of laparotomy, although in 1 case there were numerous stones in the common bile duct.

Ulcerative colitis occurred in 2 female patients aged 59 and 65 years. This diagnosis had been made on clinical, radiological and histological assessment and in both cases had been present for between 10 and 15 years. Neither had had a colectomy. One had a recurrence of diarrhoea associated with jaundice and a palpable gallbladder. The other patient presented with abdominal pain radiating to the back and associated with jaundice, with no associated symptoms of colitis.

Operations

In the no treatment group 21 patients out of 29 had a laparotomy to confirm the diagnosis.

Fifty-six patients had a palliative procedure performed. The type of operation used is shown in *Table V*. Fifteen patients underwent radical surgery; 13 of these had a partial pancreaticoduodenectomy. The mean age of this group was 58·5 years (range 40–75) and some details of these patients are summarized in *Table VI*. The usual mode of reconstruction was end-to-end choledochojejunal anastomosis, an end-to-side pancreaticojejunostomy and a gastroenterostomy distal to these anastomoses. Neither antrectomy nor vagotomy was carried out as a routine. One patient had a two-stage procedure.

Results of treatment

No treatment group

There were 29 patients in this group who had a mean disease duration (from first symptom to death) of 9 months. The mean survival after diagnosis was 2 months. Twelve patients had tumours in the body or tail of the pancreas. The other 17 patients had

tumours in the head of the pancreas. There was no difference in the length of symptoms before diagnosis or in duration of disease between these two sites.

Palliative group
The 56 patients in this group had a mean survival of 11 months from the first symptom, or 8 months from operation. No patient in this group is still alive, only 7 (13 per cent) survived for 1 year and 1 (2 per cent) for 2 years following operation. Four out of 12 patients with hepatic deposits at operation survived for a further 6 months.

The operative mortality was 23 per cent. The mean age of the patients who died was 71 years, compared with 63 in those who survived.

Complications following palliative surgery are shown in *Table VII*. The most significant of these complications was the subsequent appearance of duodenal obstruction. Out of 49 patients at risk, 7 (14 per cent) had a subsequent laparotomy for symptoms of duodenal obstruction. All were improved by a gastro-enterostomy. A further 6 patients died with symptoms suggestive of duodenal obstruction. The onset of these symptoms was from 1 to 13 months after the biliary diversion but usually between 4 and 6 months. Most of these patients had had disease confined to the pancreas at the initial laparotomy but 2 had had peritoneal deposits and 2, hepatic deposits. One of the 7 patients having a gastro-enterostomy as a second procedure died before leaving hospital. The remainder lived, free of obstructive symptoms, for between 2 and 12 months. Although vagotomy was not carried out, no patient had subsequent symptoms of anastomotic ulceration.

Radical surgery
Operative mortality: There were 4 operative deaths in the 13 patients who underwent pancreacticoduodenectomy. In 1 patient the cause of death was not recorded but her condition remained poor throughout the postoperative period and she died on the fifth day. Two patients died of haemorrhage; one from operative damage to the portal vein. The other died on the fourth day; at post-mortem examination bleeding was found in association with a necrotic pancreaticojejunostomy. The fourth patient who died collapsed suddenly on the tenth postoperative day. At post-mortem he was found to have had a massive pulmonary embolus. All the anastomoses were found to be intact.

The mean age of the patients who died was 65 years compared with 55 years for those who survived the operation. Only 1 patient older than 70 years survived and only 1 patient younger than 65 years died (*Table VIII*).

The mean serum bilirubin level in the patients who died was 18 mg per cent and in those who survived 10 mg per cent. No patient with bilirubin below 10 mg per cent at the time of operation died (*Table VIII*).
Late results: Nine patients survived for longer than 1 month after the operation. Five patients have since died at a mean of 11 months (range 5–18) after operation. It is assumed that all these patients died from recurrence although histological proof was not always available.

Four patients are still alive and clinically recurrence-free between 12 and 44 months (mean 32) later. If all these patients died now the mean survival following successful operation would be 21 months.

Late complications apart from recurrence have been few. There have been no examples of anastomotic ulcer. One patient has steatorrhoea which is satisfactorily controlled by pancreatic extract. One patient has had a single episode of ascending cholangitis.
Other radical procedures: One patient had a transduodenal excision of an ampullary lesion and died of a myocardial infarct 3½ years later. There was no clinical evidence of recurrent disease although a post-mortem was not held.

One patient had an excision of the tail of the pancreas for carcinoma. She died in the early postoperative phase. Permission for a post-mortem examination was not obtained and the cause of death was not established.

Discussion

This group of patients does not seem to differ significantly from other recently published series (e.g. Grieve, 1973) in respect of the site of the tumour and age. However, the sex ratio is more nearly 1 : 1 than is usually recorded and this does not seem to be related to age or the site of the tumour, as suggested by Wynder et al. (1973).

The occurrence of 15 cases of diabetes mellitus raises the possibility of there being a causal relationship between the two diseases. The usually quoted incidence of diabetes mellitus in the general population is between 1–2 per cent and rising with age (Sonksen, 1972). However, Butterfield (1964) suggested that the prevalence is 12–14 per cent, although his criteria for diagnosis depended on the response to a heavy glucose load. Wynder et al. (1973) have shown a significant correlation between diabetes mellitus and pancreatic carcinoma in females but not in males. Other evidence from the present series in favour of at least a casual relationship is the close temporal relationship in the onset of the two diseases and the observation that longstanding diabetics have become unstable shortly before other symptoms have occurred. Walker (1970) reports a case of an abnormal glucose tolerance test reverting to normal after successful pancreaticoduodenectomy. Baron and Nabarro (1973) found 2 cases of carcinoma out of 14 cases of maturity-onset diabetes after subjecting them to extensive investigations. It would seem wise to consider a change in diabetic status as a possible warning of pancreatic carcinoma.

The 14 per cent of patients with gallstone disease probably reflects the prevalence in the community rather than a real association (Rains, 1964). The main interest in this group is the diagnostic problem; it is worth noting that 3 patients had had common duct stones removed at previous laparotomy and, not surprisingly, their subsequent obstructive jaundice had been attributed to recurrent calculi. In view of the possible association between ulcerative colitis and carcinoma of the biliary tract (Ross and Braasch, 1973), it is interesting to note two such instances in the present series.

There is insufficient material to analyse the relative merits of the different procedures used, but in general cholecystoduodenostomy has given satisfactory biliary diversion and has been easy to perform. Subsequent duodenal obstruction does not appear to be associated with a recurrence of jaundice.

Duodenal obstruction has been a significant complication following successful biliary diversion. It is suggested from these results that a gastro-enterostomy should be added to the procedure in all cases. Liver deposits need not be a contra-indication because some of these patients survive 6 months or more. The addition of this procedure adds to the operating time but will spare 1 patient in 5 unpleasant and avoidable symptoms, only relieved by a further operation.

The 13 per cent 1-year survival following palliative surgery does not differ greatly from other series (Gill et al., 1970). Although recurrent jaundice has not been a major problem, the useful palliation achieved has been very limited.

The mortality for pancreaticoduodenectomy in this series is 31 per cent, but the deaths mainly occurred in the earlier years of the survey and the only patient to have died in the last 7 operations did so from a pulmonary embolus.

The late results are poor but 4 patients are still alive and well. The impression has been gained that longer and better palliation has been given to those who have died.

The critics of pancreaticoduodenectomy point to the high operative mortality, the low cure rate and prolonged hospitalization (Crile, 1970). In this series some of these criticisms appear to be unfounded. There is no increase in hospital stay for those having radical surgery (*Table IX*). The mean survival time of 21 months compares with 8 months. In addition, 4 patients are alive and well with 2 having survived 3 years and 2 are still alive between 1 and 2 years later. Only 1 patient has survived 2 years following palliative surgery.

Two-stage procedures have not been prominent in this series, but the relation of mortality to the bilirubin levels above 15 mg per cent suggests that this approach might be considered more often.

Despite its many problems, pancreaticoduodenectomy in selected cases still seems the most satisfactory method of treatment at present available. The decision in part depends on the surgeon's personal philosophy. He has to balance a higher operative mortality, the chance of a major operation for mistaken diagnosis and the chance of a curative operation against a short survival with relief of jaundice and the occasional pleasant surprise when the diagnosis proves to be wrong.

Table IX: COMPARISON OF PALLIATIVE AND RADICAL SURGERY

Surgery	Operative mortality (%)	Mean postoperative survival (mth)	Days in hospital
Radical	31	20	20
Palliative	23	5	25

In Wales there are about 250 cases of pancreatic carcinoma annually (Registrar General, 1971). If the figures in this series are representative, each consultant may be faced by a technically operable lesion once in every 18 months.

Four main conclusions may be drawn from this series:

1. Maturity-onset diabetes should alert the clinician to the possibility of an underlying carcinoma.
2. Pancreaticoduodenectomy was performed in about 15 per cent of cases and appears a worthwhile procedure.
3. Painless jaundice is associated with a higher resection rate.
4. Palliative procedures should include a gastro-enterostomy in addition to a biliary diversion.

Acknowledgement

I should like to thank Mr H. G. Roberts for his permission to study his patients and for his help and encouragement.

A comparison of one layer and two layer techniques for colorectal anastomosis

W. G. EVERETT*

SUMMARY

In a randomized prospective clinical trial one layer and two layer techniques have been compared in 92 patients undergoing colorectal anastomosis. The results were assessed radiologically by barium studies on the tenth postoperative day. There was no significant difference in the incidence of anastomotic breakdown with either technique when the anastomosis was performed above the pelvic peritoneal reflection. When the anastomosis was situated below the pelvic peritoneum the incidence of dehiscence was significantly greater when a two layer technique was used.

BREAKDOWN of the anastomosis is still the most significant complication of surgery of the large bowel and accounts for more deaths than any other single cause. The incidence of this complication is highest for colorectal anastomosis, especially when this is performed below the pelvic peritoneal reflection.

There is still doubt concerning the safest method of anastomosis. End-to-end anastomosis, performed in two layers with inversion of the bowel edges, has become the generally recommended technique (Goligher, 1967; Muir, 1969; Turnbull and Kyle, 1969). Nevertheless, some surgeons have found that a single layer anastomosis gives equally satisfactory results (Gambee et al., 1956; Beling, 1957; Trimpi and Kratzer, 1959). Experimental studies have been conflicting (Letwin et al., 1967; Loeb, 1967) and experiments in animals are not always applicable to the situation in man. Recently, Irvin et al. (1973) published the results of a clinical trial of single layer and two layer anastomoses. Their study included patients in whom many different types of operation were performed, involving anastomosis of both the large and small bowel.

It is considered that further data are necessary on this subject and the results of an additional controlled trial in patients undergoing colorectal anastomosis are reported.

Materials and methods

Ninety-two patients undergoing elective resection of the large bowel and end-to-end colorectal anastomosis were studied (*Table I*).

Table I: PRESENT SERIES

Technique	Anastomosis High	Anastomosis Low
One layer	29	11
Two layer	38	14
Total	67	25

The patients were admitted to hospital 48 hours before operation and given a low residue diet. The bowel was prepared by soap and water enemas on the 2 days prior to surgery. A rectal washout was performed on the day of operation and repeated, if necessary, until the washings were clean. No form of antibiotic bowel preparation was used.

All the patients were operated on by the author. The decision to include a patient in the series or not was made only after the bowel had been resected and when it had been ascertained that an intra-abdominal anastomosis could be performed by either technique. Eight patients were excluded and do not form part of the series; in 5 a colo-anal anastomosis was performed; in 3 it was considered that it was only possible to perform a single layer intra-abdominal anastomosis so low in the pelvis. When the decision to include a patient in the series had been made the type of anastomosis to be employed was chosen by a method of random selection.

The single layer anastomoses were performed with interrupted stitches of 4/0 Supramid, passing through all coats of the bowel wall. Nine sutures were used for the back layer and all the stitches were inserted before the proximal bowel was brought down into the pelvis. The back layer stitches were tied with the knots on the inside of the bowel. Gambee-type sutures (Gambee et al., 1956), inverting the mucosa, were used for the front layer.

The two layer anastomoses were constructed with continuous 2/0 chromic catgut for the all-coats stitch, and interrupted Lembert sutures of 4/0 Supramid for the seromuscular layer. The seromuscular stitches of the back layer were inserted first, in a manner similar to that already described for the one layer technique. The inner layer was then sutured with continuous catgut and the front of the anastomosis completed with interrupted Lembert sutures of Supramid. The suture line was marked with two Cushing's clips to aid in its location during subsequent barium examination. In all cases a silicone drain was placed down to, but not in contact with, the anastomosis and allowed to drain freely into a Urebag. The drain was removed on the seventh postoperative day.

In each case the level of the anastomosis was recorded according to its position in relation to the pelvic peritoneum. If situated above or at the level of the peritoneal reflection it was classed as a 'high'

* Confirmed by laparotomy.
† Confirmed by barium enema.
‡ Confirmed by post-mortem.

colorectal anastomosis, even though in many instances the rectum was mobilized posteriorly to facilitate fashioning of the anastomosis. When performed below the peritoneal reflection it was termed a 'low' colorectal anastomosis. A covering right transverse colostomy was performed in all but one case of low anastomosis. The amount of faecal loading of the bowel and the degree of contamination occurring during the operation were recorded.

In the postoperative period all cases were given 0·5 g streptomycin 12-hourly and 1 million units of penicillin 6-hourly for 4 days.

The results were assessed by a clinical evaluation, and a limited barium enema examination was performed on the tenth postoperative day to assess the integrity of the anastomosis. Sigmoidoscopy and digital examination of the suture line were avoided.

Results

It is well recognized that the incidence of dehiscence is much greater for low than for high colorectal anastomoses (Goligher et al., 1970). The results have therefore been assessed according to the site of the anastomosis, and are described as 'high' or 'low' according to whether the suture line was above or below the pelvic peritoneal reflection.

Comparability of the groups

Factors which may be relevant to anastomotic dehiscence are age, sex, pathology, faecal soiling, faecal loading of the bowel and the presence or absence of a colostomy before or after surgery. The details of the two groups in which a one layer or two layer technique of anastomosis was used are shown in *Table II* for high anastomoses and in *Table III* for low anastomoses.

Table II shows that the two groups are well matched in all respects except for the pathology. There were more cases of carcinoma in the one layer group and more cases of diverticular disease in the two layer group.

In the low anastomoses (*Table III*) there were differences with respect to age and sex between the two groups which will be referred to later.

Incidence of dehiscence of the anastomosis

Anastomotic dehiscence was detected by clinical and radiological assessment. The results are shown in *Table IV*.

In 4 cases leakage of the anastomosis was suspected on clinical evidence or found at post-mortem. There was 1 death in the immediate postoperative period from ischaemic heart disease, and post-mortem examination revealed a partial breakdown of the suture line. One patient developed peritonitis, and a complete breakdown of the anastomosis was found on re-exploration. In 2 patients anastomotic dehiscence was suspected; one because of pain, and the other on account of a purulent discharge from the drain to the anastomosis. Leakage was confirmed in both cases by barium studies.

Of the 92 patients, barium studies were performed in 90; X-rays were not performed on the 2 patients who came to laparotomy or post-mortem. Of the 90 barium examinations, 2 were unsatisfactory in showing the anastomosis; one because of apparent, but temporary, obstruction at the suture line, and the other because of faeces in the bowel.

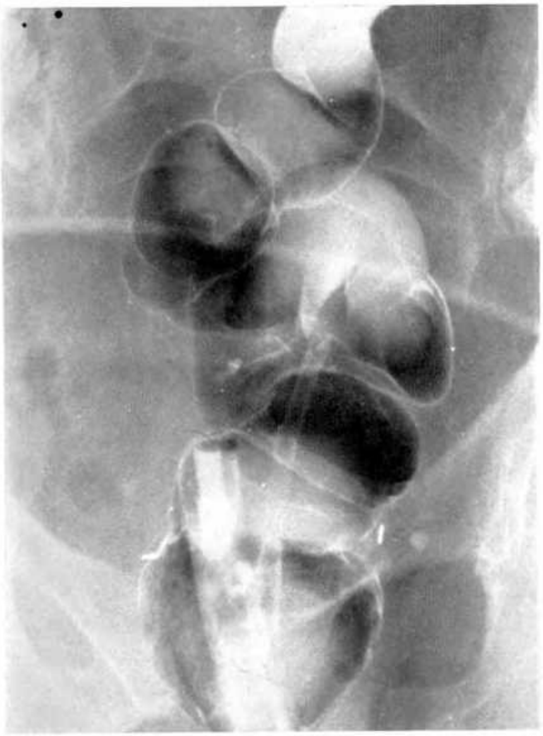

Fig. 1. Low anastomosis, one layer technique.

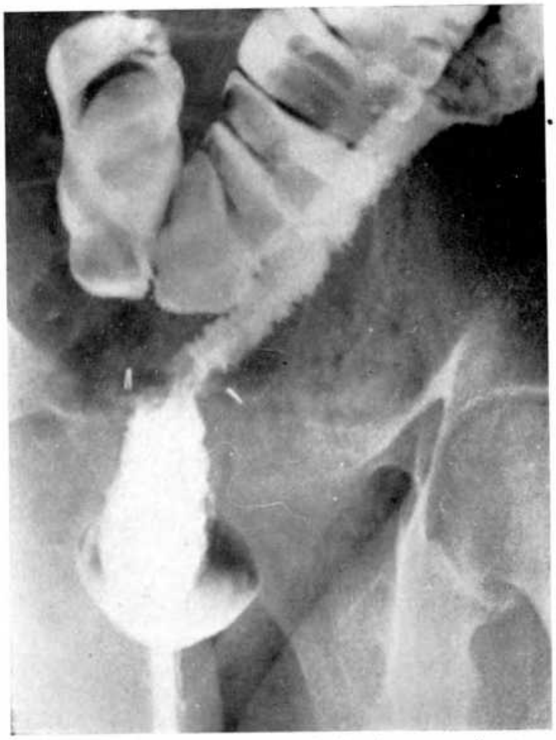

Fig. 3. High two layer anastomosis showing narrowing at the suture line caused by the inturned flange.

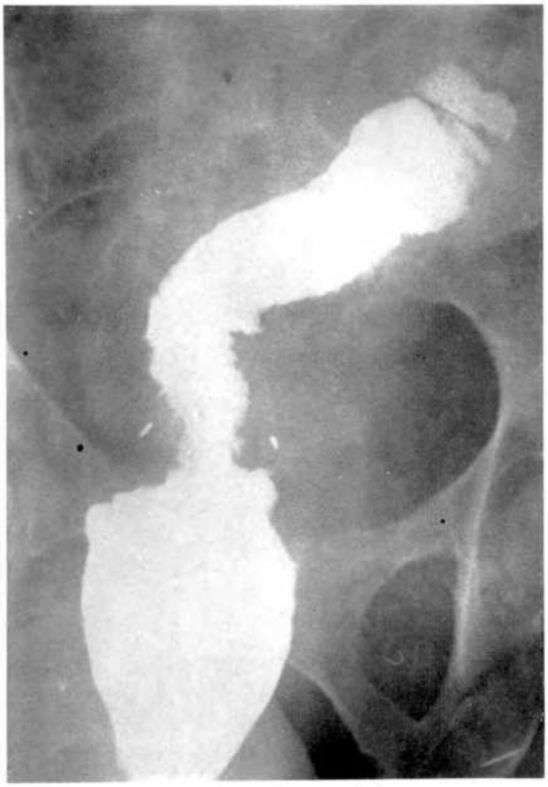

Fig. 2. Low anastomosis, two layer technique.

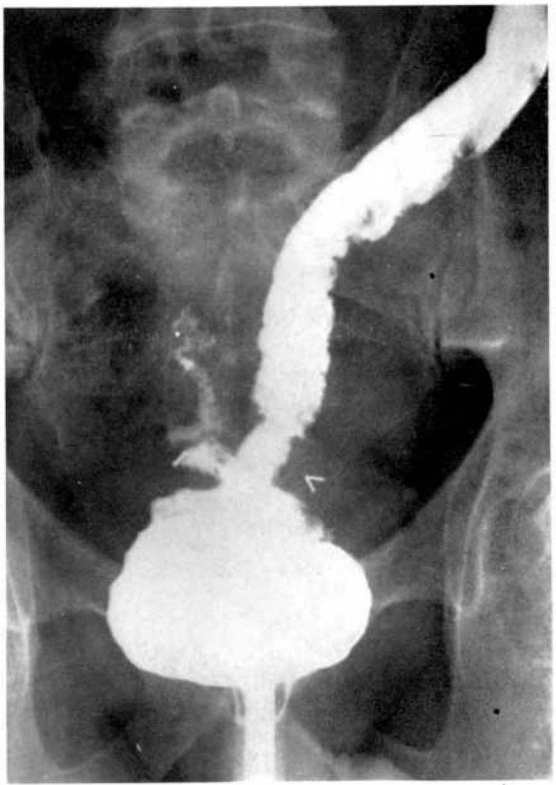

Fig. 4. Low two layer anastomosis showing leakage of average extent.

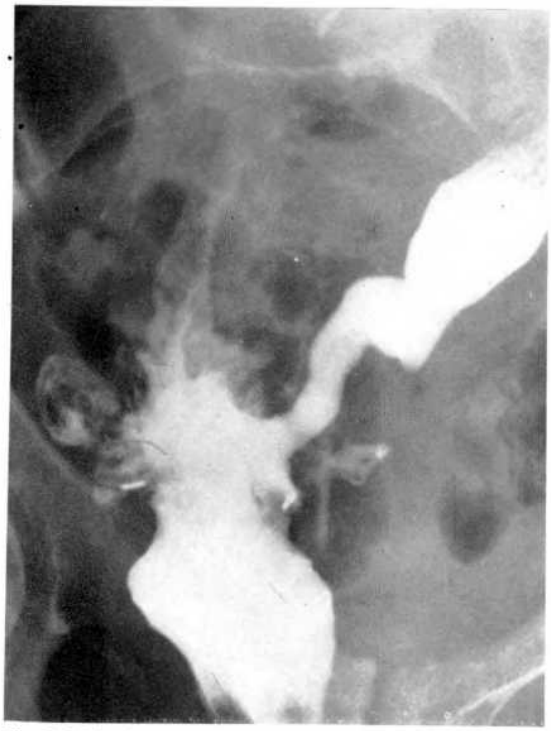

Fig. 5. Major leakage occurring in a low anastomosis (with covering colostomy) with no symptoms or signs.

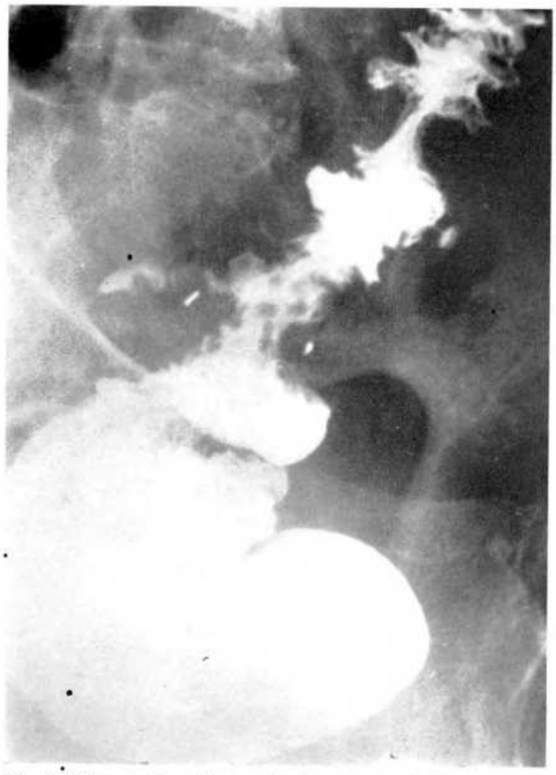

Fig. 6. Minor leakage from a high anastomosis diagnosed clinically.

When assessed radiologically there was no significant difference between the one layer and two layer techniques for high anastomoses ($\chi^2 = 0{\cdot}003$). For low anastomoses a two layer technique was associated with a significantly greater incidence of leakage ($\chi^2 = 3{\cdot}956$, $P < 0{\cdot}05$).

The total dehiscence rate for each group was assessed from the radiological and clinical evidence of anastomotic breakdown. No difference was found between the two groups where a high anastomosis had been performed ($\chi^2 = 0{\cdot}019$). The incidence of breakdown was significantly greater in patients with a low anastomosis in whom a two layer as opposed to a one layer technique had been used ($\chi^2 = 4{\cdot}73$, $P < 0{\cdot}05$).

Dissimilarities in the groups

In the high anastomoses there was a dissimilarity of pathology, particularly with regard to the number of cases of carcinoma and diverticular disease, in each group (*Table II*). In the random allocation there was a significantly greater number of patients with carcinoma who had a one layer anastomosis ($\chi^2 = 4{\cdot}2$, $P < 0{\cdot}05$) and this could be considered prejudicial. However, no significant difference was found when the leakage rate was compared in patients operated on for carcinoma with those having diverticular disease ($\chi^2 = 0{\cdot}004$). It is therefore concluded that there is no difference in the results of using a one layer or a two layer technique for anastomoses above the pelvic peritoneum.

In the patients who had low anastomoses there were dissimilarities of age and sex in the two groups. A younger average age was found in the two layer group, but this gave a favourable bias to the group which did worst. There were considerably more men than women in the two layer group. It could be argued that it is technically more difficult to perform a low anastomosis in a man and this might explain the higher leakage rate in this group. The converse was true for the one layer group. Statistical analysis failed, however, to show a significant difference in the distribution of men and women in the one layer and two layer groups ($\chi^2 = 1{\cdot}062$). The leakage rate was not influenced by sex in the two layer group ($\chi^2 = 0{\cdot}112$), or in the total series of low anastomoses ($\chi^2 = 0{\cdot}98$).

Radiological appearance of anastomoses

The site of anastomosis would have been difficult to locate with accuracy in several cases if it had not been marked with Cushing's clips. In general, the anastomoses performed with the one layer technique (*Fig.* 1) were wider than those in which a two layer technique had been used (*Fig.* 2). In some cases there was quite a marked flange produced by the two layer technique (*Fig.* 3) with apparent narrowing of the bowel lumen. This was not seen with one layer anastomoses. The slight narrowing of the two layer anastomoses did not appear to be of any importance. In one patient who had a one layer anastomosis there was obstruction of the flow of barium at the suture line and the examination was therefore abandoned. There was, however, no clinical evidence of obstruction in this case or in any other patient. Late obstructive symptoms developed in one patient who had a high two layer anastomosis. A barium enema on the tenth postoperative day showed a wide anastomosis with a small leak. Subsequent X-rays demonstrated a fibrous stricture at the suture line which was later resected.

The majority of radiological leaks were of a fairly minor degree and their extent was, in most cases, similar to that shown in *Fig*. 4.

There was no correlation between the extent of the leakage, as assessed radiologically, and the clinical picture. In some cases very large leaks occurred without pain, elevation of temperature or drainage of pus or faecal fluid from the drain site (*Fig*. 5). The minor anastomotic leak shown in *Fig*. 6 was, however, diagnosed by the presence of pain, pyrexia and abdominal tenderness.

Discussion

Dehiscence of the anastomosis is the most significant complication of colorectal anastomosis. It accounts for more deaths than any other single cause (Everett, 1970). The incidence of dehiscence following low colorectal anastomosis was found by Goligher et al. (1970) to be almost 70 per cent, when this was assessed by digital palpation, sigmoidoscopy and barium examination. For this reason it is generally felt that low restorative resections must be accompanied by a protecting transverse colostomy.

The safest method of performing an anastomosis has been a matter of dispute. Most surgeons recommend an inverting technique using two layers of sutures (Goligher, 1967; Muir, 1969; Turnbull and Kyle, 1969), but for many years others have advocated anastomosis with a single layer of sutures (Maunsell, 1892; Gambee et al., 1956; Beling, 1957; Trimpi and Kratzer, 1959). In a retrospective study of 437 anastomoses Buchin and Van Geertruyden (1960) concluded that there was a lower incidence of dehiscence with a single layer technique. A prospective clinical trial of single layer and two layer anastomoses has recently been performed by Irvin et al. (1973). Several different types of anastomosis were performed including ileoileal, ileocolic, ileorectal, colorectal and colocolic. There were no low colorectal anastomoses in the series. The incidence of dehiscence in the single layer group was 17 per cent, and 16 per cent in the two layer group. The conclusion was that there was no advantage in either one of these methods over the other.

In the present study no significant difference was found between one layer and two layer techniques when the anastomosis was performed above the pelvic peritoneal reflection. The incidence of dehiscence (15 per cent) was very similar to that of Irvin et al. (1973). The leakage rate was considerably greater when a two layer technique was used for low colorectal anastomosis. There are two possible explanations for this:

1. The blood supply to the rectal stump might be rendered precarious through mobilization and ligation of the middle rectal arteries. In these circumstances a double layer of stitches could cause ischaemia of the suture line where a single layer might not. In practice, there is usually brisk bleeding from the rectal stump and its blood supply appears to be as good as that of the colon to which it is being joined.

2. As pointed out by Halsted (1887), there is only one layer of the bowel wall which has any substantial strength and this is the submucosa. The muscle layer of the rectal stump holds stitches poorly, perhaps because of the absence of a serosal layer. It is therefore even more important in anastomosis of the rectum that every stitch should pick up the submucosa. With a one layer through-and-through stitch the submucosa is included with certainty in every bite. When a two layer anastomosis is performed low in the pelvis, placing the stitches accurately is not easy and it is especially difficult to ensure that the submucosa is included in the Lembert stitches. This applies particularly to the back layer of the anastomosis, and it is perhaps significant that, in the experience of the author, this is the common site of leakage from the suture line.

It is undoubtedly true that it is much easier to perform an anastomosis in the pelvis with one layer of stitches than with two, and when the suture line is extremely low an anastomosis can sometimes only be achieved by a one layer technique.

In the experience of the author, a one layer technique gives better results than a two layer method for low colorectal anastomosis, and the accuracy with which the sutures are placed seems to be of particular importance.

Acknowledgements

I am indebted to Dr F. R. Berridge and his colleagues of the Radiology Department, Addenbrooke's Hospital, Cambridge, for performing the radiological studies, Mr F. H. J. Beard of the Department of Medical Photography for the illustrations and Mr D. Sampson for help with the statistical analysis.

Complete disappearance of popliteal arterial thromboses in 2 patients

KENNETH BLOOR AND VICTOR COPE*

SUMMARY

Two young male patients with complete spontaneous resolution of popliteal thrombosis are described. The thromboses had been present for roughly 3½ and 4 months. Such resolution has not been previously reported. The cause of the lesions is unexplained. It is suggested, should such a lesion be encountered, that the correct treatment is exploration to exclude adventitial cysts and popliteal entrapment, and simple evacuation of clot and anticoagulation.

TOTAL spontaneous resolution of an arterial thrombosis does not appear to have been previously reported. In the 2 cases to be described, popliteal thrombosis present for 3 months or more resolved completley. In both cases the presence and disappearance of the thrombosis were proved by arteriography.

Case reports

Case 1: J. W., an 18-year-old male, was a keen footballer, and after playing in a match on 15 January 1962 noticed tiredness of his right leg. No injury to the leg was remembered. Thereafter he had gradually increasing pain behind the knee, radiating into his calf on walking. His right foot also went cold and numb on exercise. He was a non-smoker. He was seen in the Vascular Clinic of Manchester Royal Infirmary on 22 February 1962, when pulses were absent at the right ankle and oscillometry demonstrated reduced pulsations below the knee on the right side. Between this attendance and his admission on 3 March his symptoms disappeared, and on admission pulses were present at both ankles and oscillations were equal and good in both legs. There was no clinical evidence of heart disease and the electrocardiogram was normal. Other investigations did not reveal any abnormality. His erythrocyte sedimentation rate, haemoglobin and white cell count were normal. His serum cholesterol was 225 mg/100 ml. On exercise on a walking machine he had no pain at 2½ m.p.h. after half a mile. The speed was increased to 3½ m.p.h. for a further half a mile without pain. He was discharged without treatment.

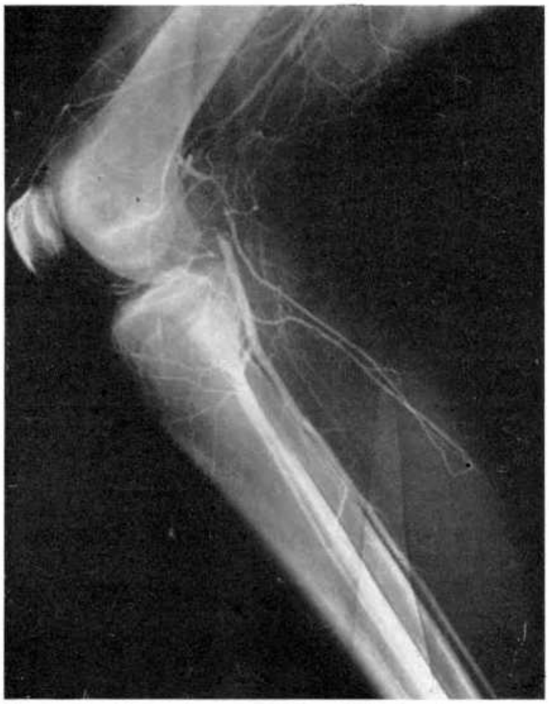

Fig. 1. *Case* 1. Arteriogram, 30 May 1962, showing upper popliteal thrombosis.

For 2 weeks after discharge he had no trouble, but after a game of football the pain in the calf and cold foot on walking recurred, and on readmission on 21 May 1962, pulses were absent and oscillations reduced below the knee in the right leg. A right femoral arteriogram was performed by cutdown on the common femoral artery on 30 May 1962 (*Fig.* 1). This showed a block about 5 cm in length in the upper popliteal artery. There was no recanalization, and there was a good collateral circulation. On walking at 2½ m.p.h. pain occurred after 700 yards and he was halted at 1100 yards after the speed had been increased to 4 m.p.h. In view of the mild nature of his claudication no treatment was offered. Shortly after discharge from hospital his claudication disappeared again. A further arteriogram was performed on 28 September 1962 (*Fig.* 2). This demonstrated patency of the popliteal artery, which appeared normal apart from a slight irregularity and a small filling defect immediately above the femoral condyles. Thus, on the second occasion his thrombosis was present for more than 2 months. He was discharged without treatment.

He was seen again on 12 May 1966 for an unrelated complaint. He had had no recurrence of intermittent claudication since 1962 and his right ankle pulses were present. All investigations including an electrocardiogram were normal. His serum cholesterol was 240 mg/100 ml. Efforts to trace him since then have unfortunately failed.

Case 2: B. B., a 35-year-old male, worked as a fireman. Both at work and at home whilst doing odd jobs he was in the habit of sitting on his right leg with the knee bent and the lower leg underneath his left thigh. He had a family history of arterial disease in that his father suffered from angina pectoris. The patient was a non-smoker.

His symptoms started suddenly shortly after he had been sitting on his right leg for 2–3 hours whilst working in July 1971. Initially his intermittent claudication was not severe but it gradually worsened until he was only able to walk 30 yards, and by the end of September 1971 he had begun to have typical nocturnal rest pain in his right foot which was relieved by hanging the foot over the side of the bed. He was admitted on 25 October 1971. His blood pressure was within normal limits at 140/90. He had no clinical evidence of arterial disease apart from the absence of pulses at the right ankle. The foot was markedly pale on elevation and there was diminution of sensation to a pin prick. An arteriogram showed a normal arterial tree apart from a short popliteal thrombosis

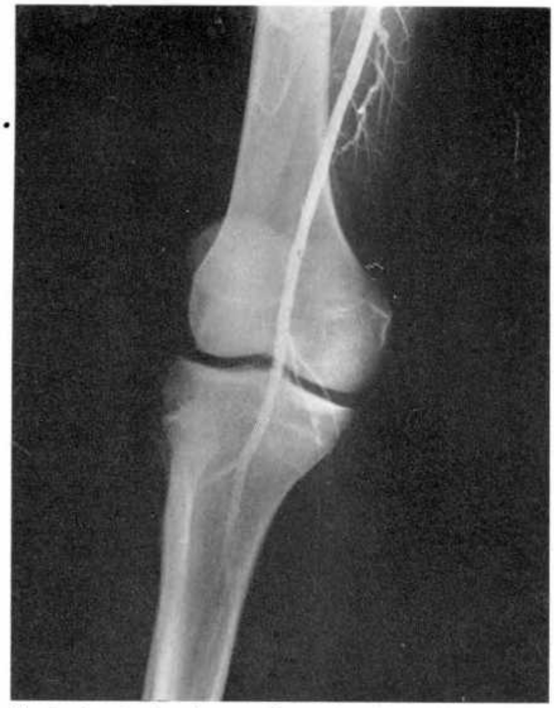

Fig. 2. *Case* 1. Arteriogram, September 1962, showing resolution with a small filling defect at the level of the adductor tubercle.

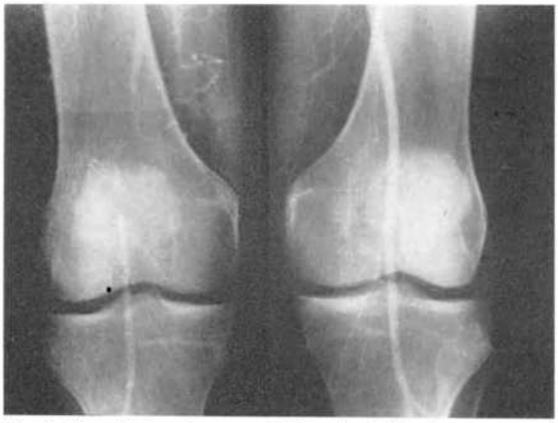

Fig. 3. *Case* 2. Arteriogram, 25 October 1971, showing upper popliteal thrombosis on the right side.

in the right leg about 2 cm in length and about 4 cm above the knee joint (*Fig*. 3).

In view of his youth and the short time since the commencement of his symptoms it was considered that operative treatment should not be undertaken immediately and he was discharged. The patient's rest pain disappeared that evening. His intermittent claudication improved and he was able to walk a mile without pain at review a month later.

He was readmitted in January 1972 for a repeat of the peripheral arteriograms. This showed complete restoration of the arterial lumen (*Figs*. 4, 5) apart from a small filling defect in the artery similar to that seen in the previous patient. On this admission his blood count was within normal limits, the haemoglobin was 14·7 g and the platelet count was 220 000/mm³. Coagulation studies showed no abnormality in the plasma clotting time, the prothrombin time and the plasma fibrinogen, which was 334 mg/100 ml. The fibrinolytic system appeared to be normal in that the euglobin lysis time was 300 minutes and fibrin degradation products were within the normal range. Total serum cholesterol was 200 mg/100 ml and the serum lipoprotein pattern in the fasting state was normal. When seen in the outpatients' department on 17 March 1973, the patient was able to walk indefinitely without pain at a normal pace and all peripheral pulses were present.

He was advised to abandon his habit of sitting with his right leg bent underneath him. No other treatment was prescribed.

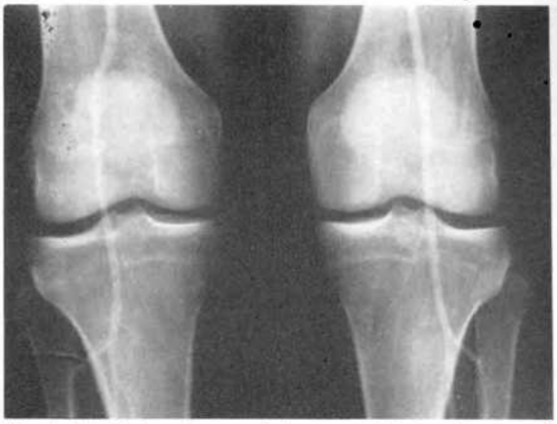

Fig. 4. *Case* 2. Arteriogram, 5 January 1972, showing resolution of the thrombus.

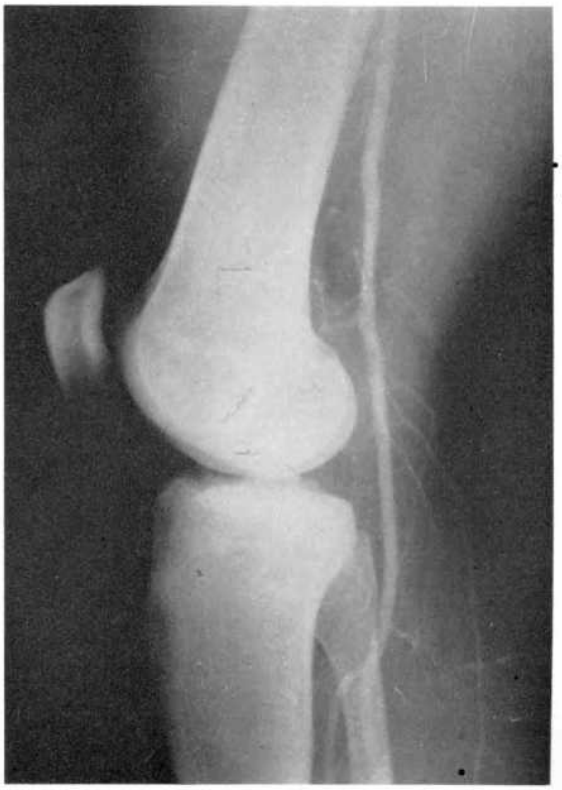

Fig. 5. *Case* 2. Lateral arteriogram, 5 January 1972, showing a small filling defect level with the top of the femoral condyles.

Discussion

Case 1 appears to have had resolution of a popliteal arterial thrombosis on two occasions. Resolution may have been incomplete in the first place but there can be no doubt about its final disappearance. Thus the patient had had partial or complete occlusion for 6 weeks initially, and complete occlusion for more than 2 months. In *Case* 2 the occlusion had been present for 4 months before disappearance. In both cases the thrombosis may be related to indirect damage to the vessel wall; in *Case* 1 both exacerbations were related to playing football and in *Case* 2 the patient attributed it to his curious habit of sitting on his leg. It is, however, difficult to suggest a mechanism for this damage with normal anatomy. Such indirect trauma could only be conceived of in the case of an anatomical abnormality, such as an aberrant muscular or fascial band.

In neither case was there any suggestion of a peripheral or central lesion which could cause emboli. The position of the block in both cases is not in the site in which one would expect an embolus, i.e. it is not impacted at a bifurcation. Complete or partial resolution of an embolus with thrombosis is not uncommon in the first 2 or 3 days. After this time, however, resorption of the clot, for reasons discussed below, is not within anyone's clinical experience.

The popliteal artery is a favoured spot for arterial occlusions and in young people there are two uncommon lesions, namely cystic adventitial disease and the popliteal entrapment syndrome, which may lead to popliteal thrombosis. Cystic adventitial disease produces a fairly sudden onset of intermittent claudication which gradually worsens. There are characteristic changes of arterial narrowing, which may be one-sided or hour-glass-shaped, immediately above the knee joint, and eventually thrombosis may occur (Lewis et al., 1967). There is no recorded case of spontaneous improvement (Haid et al., 1970). Should the associated intravascular thrombus resolve in such a case deformation of the artery would persist and would easily be visible on the post-resolution arteriograms.

The anatomical abnormality in the popliteal entrapment syndrome can be of two types (Insua et al., 1970). In type I the popliteal artery passes medially to the medial head of the gastrocnemius and underneath it. In this type there is an easily observable medial displacement of the artery, which was obviously not present in either of our cases. In type II, however, there is an abnormal fascial band running across the popliteal artery, which is normally placed. This produces a slight deviation of the artery similar, it might be argued, to that seen in *Fig*. 4. On inspection, however, the deviation in *Fig*. 4 is higher than would be expected from such a cause (cf. *Fig*. 3.27 in Eastcott, 1969). Again there is no suggestion in the literature (Insua et al., 1970, and the following discussion) that spontaneous resolution of a thrombosis associated with the popliteal entrapment syndrome has ever occurred.

If thrombosis occurs in a normal artery the organization of the clot is quite rapid. There is proliferation of the endothelium into the clot, followed subsequently by penetration by small arteries and eventually partial recanalization may occur with the development of muscle fibres and a microscopic appearance similar to an artery inside an artery. It is surprising therefore that thromboses present for 3 and 5 months respectively should not be sufficiently organized to prevent lysis. On the other hand, in abnormal arteries lysis of thromboses by streptokinase therapy has been undeniably demonstrated to occur in blocks of up to 12 months' duration, and this happens in a substantial proportion of patients (Martin et al., 1970). One can only presume that the thrombus was not organized and its disappearance was due to the action of natural fibrinolytic activity. Unfortunately *Case* 1 has been lost to follow-up and haematological investigation was not possible. In *Case* 2 no abnormality of coagulation or fibrinolytic activity could be demonstrated, although admittedly investigation was only undertaken some 3 months after the disappearance of the thrombus. In neither case was there any suggestion of an intercurrent illness or of any change in the patient's normal habits which might enhance fibrinolytic activity. The resolution of these thrombi therefore remains a complete mystery.

The condition appears to be extremely rare and no reports have previously appeared in the literature. In any case of popliteal thrombosis in a young man exploration of the popliteal fossa would be thought imperative if symptoms persisted. In such cases cystic adventitial disease or popliteal entrapment would be the most likely finding. Should the thrombosed popliteal artery be exposed, no external lesion found and atheroma appeared to be unlikely, it would be tempting to assume that the condition described here was present and that the only treatment necessary would be arteriotomy and evacuation of the clot followed by anticoagulant therapy with heparin.

Long term review of the results of rubber band ligation of haemorrhoids

DAVID M. STEINBERG, H. LIEGOIS AND J. ALEXANDER-WILLIAMS*

SUMMARY

A long term assessment (mean 4·8 years) of the value of rubber band ligation treatment for haemorrhoids has been obtained by a questionnaire answered by 125 of 147 patients. Eighty-nine per cent of patients were cured or satisfied with the results of treatment, although complete absence of symptoms was only obtained in 44 per cent. Further conservative treatment (rubber band ligation or manual dilatation) was required in 12 per cent and only 3 (2 per cent) have had a haemorrhoidectomy. Similar results were obtained for patients with the additional symptoms of pain and irritation, the presence of large skin tags and for the majority of third degree piles.

METHODS of treatment of haemorrhoids have been described since antiquity, with writings dealing with various methods of treatment dating back to the Babylonian era (Eastman, 1970). Hippocrates described the use of cautery—a treatment that must have been excruciatingly painful in the pre-anaesthetic era (Holley, 1946). In the twentieth century most treatment has been based on the use of sclerosants (injection) for minor degrees of haemorrhoids, and various methods of excision for prolapsing haemorrhoids (Goligher, 1967).

Much interest recently has been focused on newer conservative methods of treatment in the form of rubber band ligation and manual dilatation (Barron, 1963a; Lord, 1968; Groves et al., 1971). Claims have been made for symptomatic relief with all grades of haemorrhoids, but these have been made without any long term assessment.

A previous report from the Proctology Clinic, The General Hospital, Birmingham (Groves et al., 1971) showed that in a mean follow-up of 18 months, 91 per cent of patients considered that the result of rubber band ligation was excellent or had greatly improved their symptoms.

This paper is based on a subjective assessment by patients of the results of their treatment with rubber band ligation many years before. We believe a subjective or symptomatic assessment to be of more value than objective assessment on proctoscopy. The incidence of haemorrhoids in the general population is as yet unknown, but a study from the Mayo Clinic (Buie, 1960) gave an incidence of 52 per cent in an unselected series of inpatients. In our experience a large number of patients who appear to have haemorrhoids on proctoscopy have no symptoms.

Table I: SYMPTOMS BEFORE RUBBER BAND LIGATION (125 PATIENTS)

Symptom	No. of cases
Bleeding	114
Irritation	48
Pain	54
Prolapse	80
Discharge	29

Mean duration of symptoms before treatment, 4·5 years

		No. of cases
Haemorrhoids:	First degree	6
	Second degree	101
	Third degree	18
Other findings:	Skin tags	53
	Excoriation	8
	Painless fissure	3

Materials and methods

Prospective documentation of symptoms, proctoscopic findings and details of treatment was obtained for 147 patients who were treated by rubber band ligation between 1967 and 1969. All these patients were treated at monthly intervals until cessation of symptoms by the method described by Groves et al. (1971) using a Barron Ligator. In June 1973 a follow-up questionnaire was sent to each of these 147 patients. One hundred and twenty-five patients (81 per cent) have replied. The mean time since completion of their rubber band treatment was 4·8 years with a range of 3·5–6·0 years. The general practitioners of 10 patients have been contacted and it is known that only 2 have had further trouble with occasional mild irritation. The names of the remaining 12 patients lost to follow-up have been submitted to the Birmingham Regional Hospital Board statistics computer and none has been recorded as having had a haemorrhoidectomy in this region at any time since their rubber band ligation.

The analysis of the results will consider only the 125 patients of whom full follow-up details are available. All patients dissatisfied or suffering moderate or severe residual symptoms have been examined at the outpatients' clinic.

The presenting symptoms of the 125 patients are shown in *Table I*, the majority of patients presenting with bleeding and prolapse. 'Pain', usually episodic, was a feature in 44 per cent. Any patient found to have a painful fissure or fistula at the time of initial presentation was excluded from this survey. The mean duration of symptoms before treatment was 4·5 years.

The proctoscopic findings at the initial visit are shown in *Table II*. First degree piles are those remaining within the anal canal; second degree, prolapse

---

during defaecation but reducing spontaneously; third degree piles, prolapse at any time or requiring digital replacement. During the time over which these patients were treated a few other patients presenting at the clinic with gross third degree piles were subjected to haemorrhoidectomy without any attempt at conservative treatment. However, the incidence of haemorrhoidectomy in the patients referred to the Proctology Clinic over the past 2 years has been less than 4 per cent.

The rubber band ligation was usually performed as one application per session, based on the suggestion of Barron (1963a), that discomfort was minimized if only one at a time was applied. The principle was to continue treatment sessions on a monthly basis until patients were symptom free. The majority of patients required two or three sessions.

Results

In response to the first question on the questionnaire 116 patients (93 per cent) said that they considered the treatment worth while. The second question asked for a more detailed subjective assessment of the treatment. The answers are shown in *Table III.*

In answer to the question: 'What do you think of the result of the treatment?' an excellent or good result was reported by 111 (89 per cent), 12 (10 per cent) said the treatment achieved very little and in only 2 (1 per cent) were the symptoms made worse.

The patients were asked to make an assessment of individual symptoms, including severity and duration. The results are shown in *Table IV.* It was of interest that some patients considered themselves completely cured despite some occasional discomfort or even spotting of blood while others who stated that they were now symptom free classified their result as being much improved but not perfect. The majority of recurrent symptoms were those of intermittent bleeding, prolapse and/or discomfort.

Since completing the course of rubber band ligation 107 patients have received no further active treatment for their haemorrhoids, 8 (6 per cent) have required a further course of rubber band ligation and all but one are now satisfied with a good result. The mean time interval before the second course of ligation was 2 years. Six patients (5 per cent) have been treated with a manual dilatation and one has had a lateral sphincterotomy for persistent symptoms. All have since been cured or greatly improved. Only 3 patients (2 per cent) out of the 147 have required a haemorrhoidectomy.

The results of treatment of patients whose principal presentation of bleeding was complicated by irritation and/or pain were compared with those who had bleeding as a single presentation or associated with prolapse. The results are shown in *Table V.* There was no difference in terms of subjective result, of symptomatic relief or need for further treatment. Similarly 18 patients assessed as having large or third degree piles had similar results to those with intermediate or second degree ones. Patients with large skin tags suffered only slightly less good results than the remainder, with 84 per cent having a good result and 16 per cent being a little better or the same.

Table III: REPLIES TO QUESTIONNAIRE

Question: To 125 patients	Answer
As a result of the treatment are you now:	Yes
Completely cured?	54
Much improved but not perfect?	57
A little better?	9
Same as before treatment?	3
Worse than before treatment?	2

Cured or much improved	111 (89%)
Little or no improvement	12 (10%)
Worse	2 (1%)

Cured	19	91%	34	90%
Greatly improved	13		29	

A, Patients with bleeding as a single presentation or associated with prolapse; 35 patients.
B, Patients with bleeding complicated by irritation and/or pain; 70 patients.

Discussion

Before evaluating the results in this paper it is necessary to appreciate that treatment of the patients' piles has been carried out with the aim of obtaining symptomatic relief, without necessarily removing all haemorrhoidal tissue. Proctoscopic examination of asymptomatic patients after a course of rubber band ligation frequently shows evidence of residual haemorrhoids. Injection therapy, which has a similar objective, seems to show good results for first degree and smaller second degree piles. However, it is generally believed that injection produces poor results in patients with large haemorrhoids, and with all degrees of piles it is subject to a high symptomatic recurrence rate (Millegan, 1939; Barron, 1963b). Haemorrhoidectomy, which aims to excise most of the haemorrhoidal plexus of veins should produce lasting results. In a follow-up of 138 patients reviewed at 5 years after haemorrhoidectomy only 5 per cent had recurrent symptoms of pain, prolapse or bleeding, but 26 per cent complained of minor degrees of anal incontinence (Bennett et al., 1963). Despite the freedom from recurrent symptoms of piles haemorrhoidectomy is often a painful procedure; it involves the patient being in hospital for from 5 to 10 days with an additional time off work of 2–6 weeks; furthermore, it is not without complications such as secondary haemorrhage, stenosis or incontinence (Goligher, 1967).

The present survey shows that after rubber band ligation the majority (89 per cent) of patients considered themselves cured or greatly improved by the treatment. However, only 44 per cent were completely symptom free. Intermittent mild discomfort, occasional spotting of blood and an awareness of lumps at the anus were the principal residual symptoms. Nevertheless, many patients expressed themselves as extremely happy with this situation compared with their state before treatment.

Patients who suffer persistent or severe recurrent symptoms after rubber band ligation can be treated by further conservative measures; 15 patients (12 per cent) had either a further rubber band ligation, an anal dilatation or a lateral sphincterotomy. Only one patient required a haemorrhoidectomy due to failure of the technique to control symptoms. Two others have had a haemorrhoidectomy at their own request when symptoms later recurred.

The early symptomatic relief previously reported by us (Groves et al., 1971) and now the longer follow-up reported here have encouraged us to pursue a policy of treating third degree haemorrhoids by rubber band ligation, particularly in the elderly and patients whose general condition contraindicates haemorrhoidectomy. Similar experience in treating the majority of patients with haemorrhoids by this outpatient procedure is reported from the Lahey Clinic (Corman and Verdenhamer, 1973).

Rubber band ligation is a moderately effective method of treating symptoms due to haemorrhoids, with undoubted economic advantages over a conventional haemorrhoidectomy. We feel it has logistic and administrative advantages over the common conservative management, manual dilatation.

One of us (H. L.), a general practitioner who is a clinical assistant in the Proctology Clinic, has also performed 200 rubber band ligations in his group practice. It is our belief that this method of conservative management can be learnt by general practitioners and practised successfully without having to refer patients to hospital clinics. It is, of course, essential that these general practitioners should also learn to examine patients by sigmoidoscopy (to at least 15 cm from the anus) to ensure that they do not fail to detect coincident or underlying tumour or proctitis.

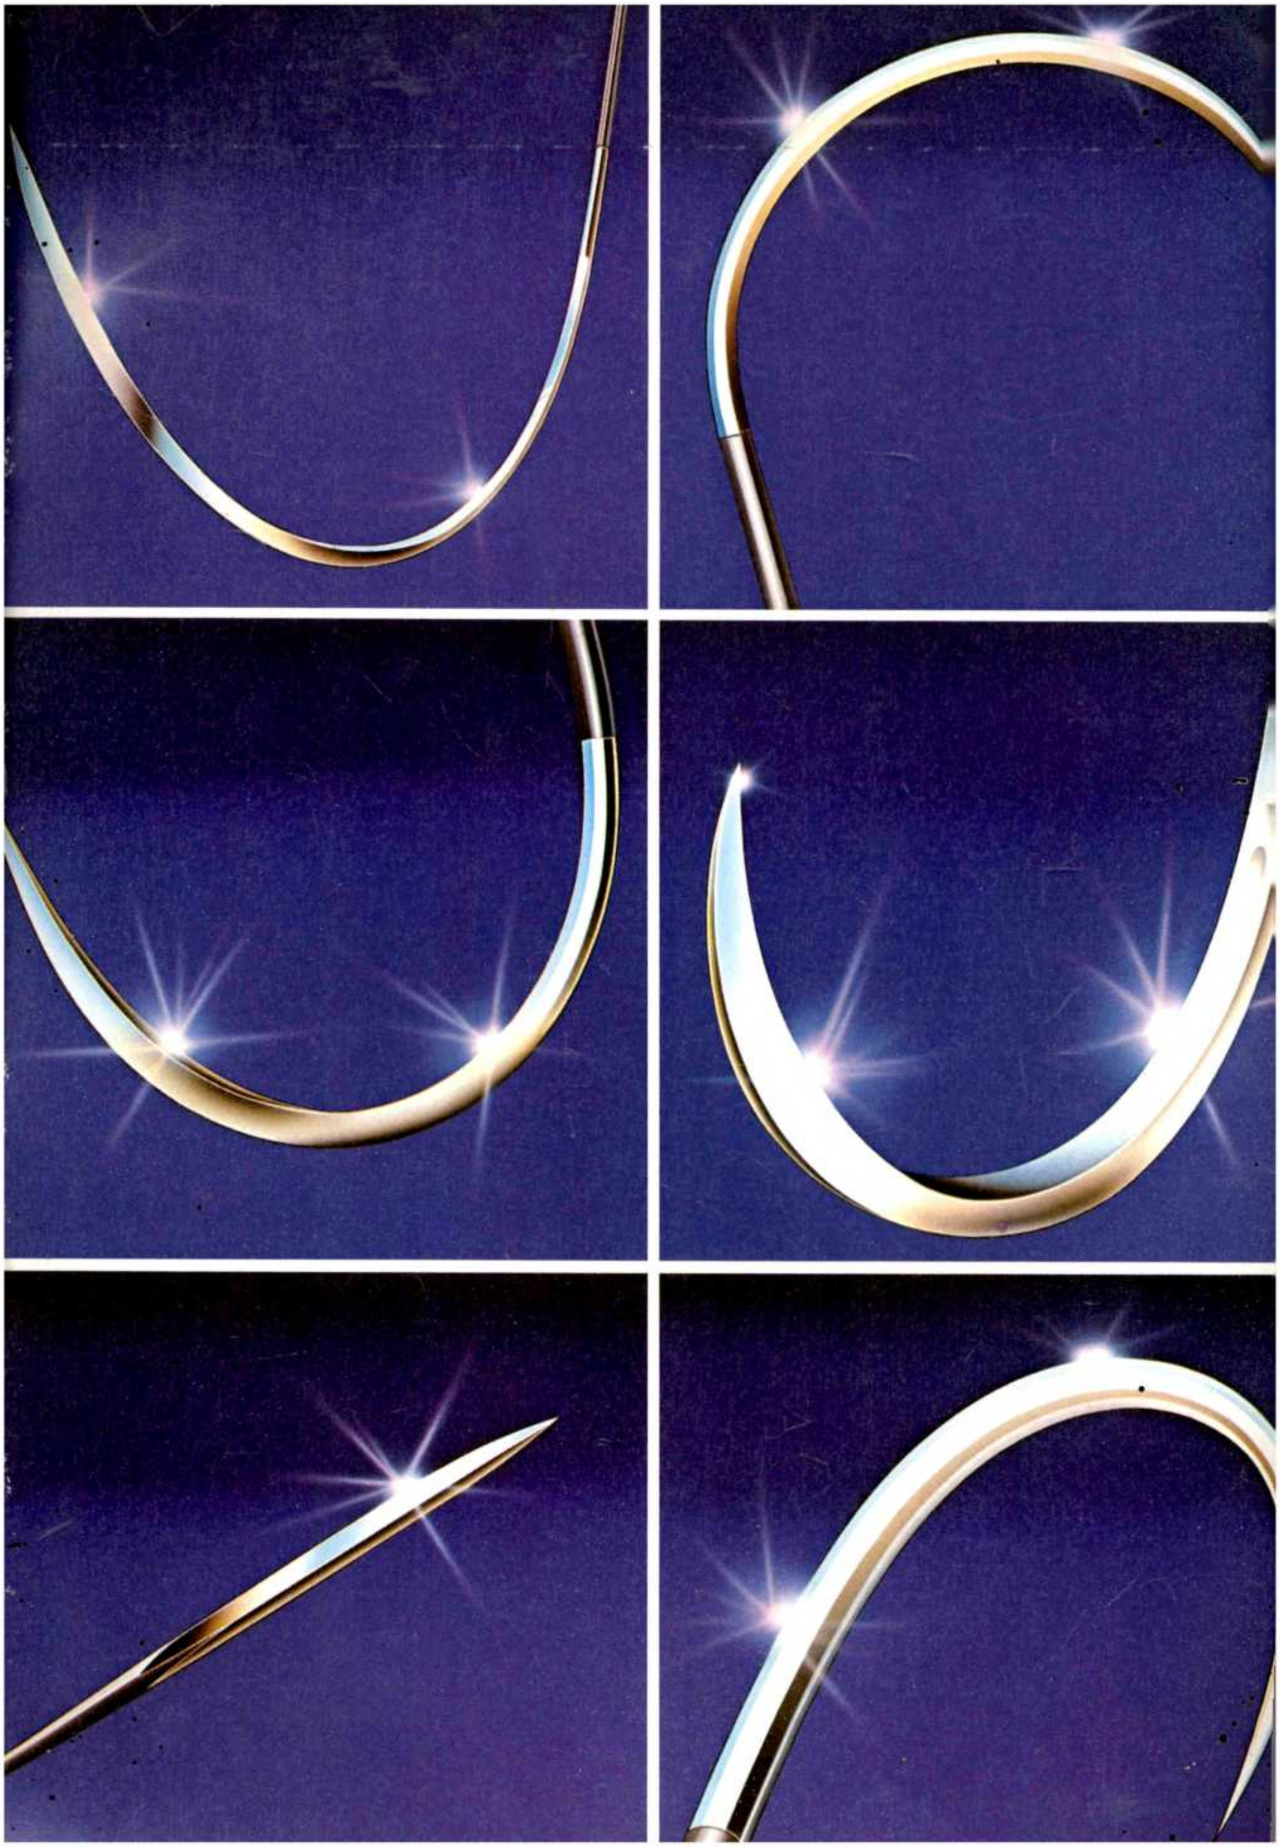
ETHICON
TRADEMARK
Eyeless needled sutures



WE MAKE SOME VERY IMPORTANT POINTS

ETHICON* Eyeless Needled Sutures offer three outstanding advantages over traditional eyed needles.

Point 1 A new sharp needle every time.

Point 2 Reduced trauma–with ETHICON eyeless needles there is no large eye and only one strand of material to pass through tissue.

Point 3 Consistent high quality–by precisely controlled manufacture of a complete sterile suture in a single package.

The choice is yours

Most surgeons agree that there is no universal suture. Most probably there never will be. Each patient, each procedure, and each layer of tissue differs from the next. This is why we at ETHICON manufacture such a comprehensive range of eyeless needled sutures.

You can choose from our wide selection of materials, absorbable and non-absorbable, securely attached to a stainless steel needle of your choice. The consistent high quality of ETHICON eyeless needled sutures provides predictable performance. This enables you to concentrate on the most critical aspect of your surgery–the well-being of the patient.

Reduce Trauma

Quality and Reliability at every stage

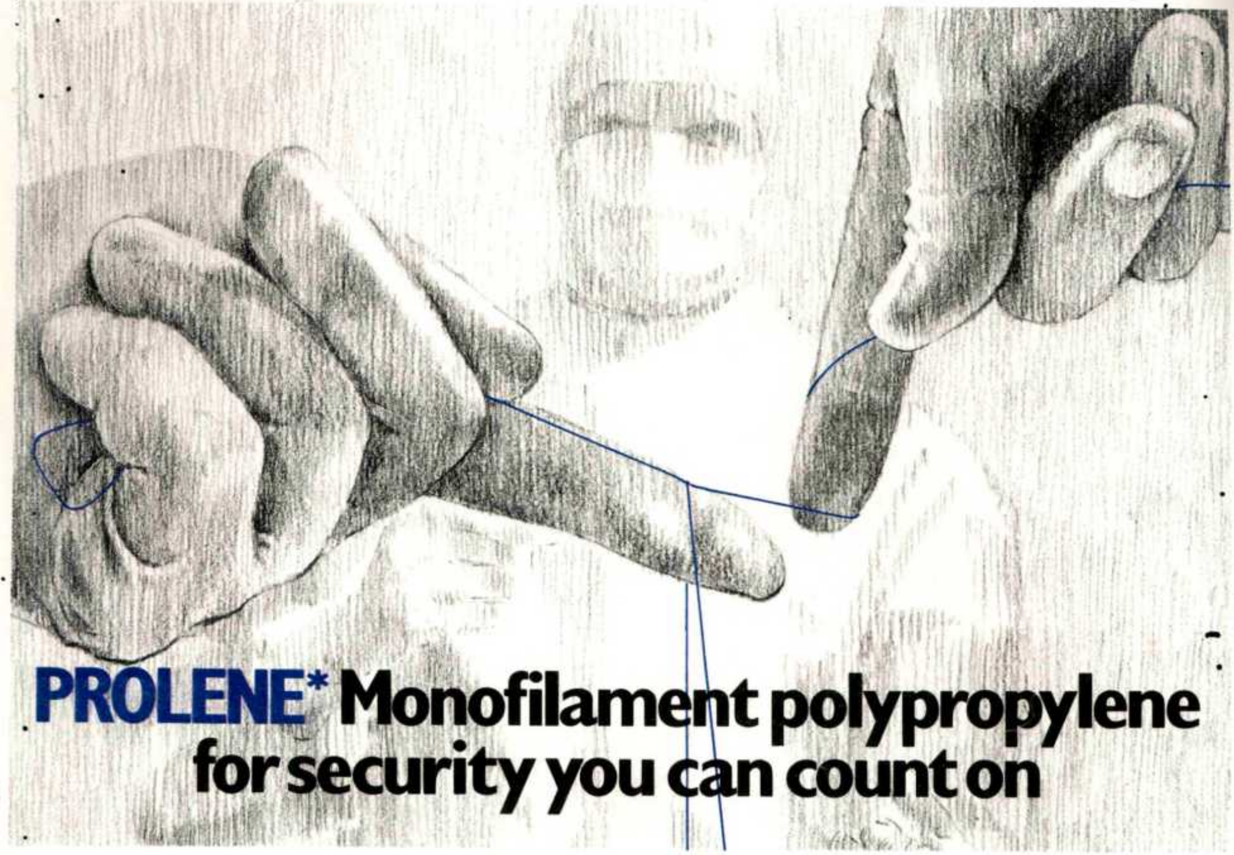
ETHICON
Eyeless needled sutures

Widest range. Finest quality

ETHICON Ltd., Bankhead Avenue, Edinburgh EH11 4HE, Scotland



PROLENE* Monofilament polypropylene for security you can count on

When the reliability of a non-absorbable is required in a contaminated or potentially contaminated field many surgeons are now choosing PROLENE suture. Made from polypropylene, a material of relative biological inertness, monofilament PROLENE suture is not degraded by tissue enzymes and is virtually unaffected by the presence of infection.

Security for extended approximation

Where wound healing may be delayed PROLENE suture can be relied on to retain its tensile strength.

Secure knot-holding

PROLENE suture is able to deform and flatten on knotting to give knot security superior to any other monofilament.

Security through reduced risk of suture extrusion and sinus formation

The specially smooth monofilament structure of PROLENE suture and its ability to tolerate infection extremely well can lessen the risk present with a braided suture in a contaminated wound.

Indications: PROLENE Polypropylene suture may be used wherever a non-absorbable surgical suture is recommended.

Precautions: Unused PROLENE sutures may not be autoclaved more than three times by the standard autoclaving method without loss of strength. Care should be taken to avoid damaging the surface of the material with surgical instruments.

Cervical spinal interbody fusion with Kiel bone

P. S. RAMANI, R. M. KALBAG AND R. P. SENGUPTA*

SUMMARY

Experience with the use of the Kiel bone graft in anterior cervical interbody fusion in cervical spondylosis is reported. The survey reviews the results of operations on 73 disc spaces in 65 consecutive patients, from 2 to 5 years after the operation. We have failed to confirm that any bony fusion in the true sense occurs with Kiel bone in anterior cervical interbody fusion. However, the aims of the operations are achieved, namely removal of the disc and osteophyte, fixation of the spine to prevent compression of the neural tissues, distraction of the adjacent vertebral bodies providing increased room in the intervertebral foramina and stability of the spine.

INTERBODY fusion of the cervical spine by an anterior approach using the Cloward technique (Cloward, 1958) is now one of the standard operations in surgery. In the early stages of our experience of the operation, in common with that of others using autografts from the iliac crest, there was a higher degree of morbidity from the donor site than anticipated. Discomfort in the area involved, often amounting to pain, was a consistent factor delaying discharge from hospital and prolonging convalescence. Change to an alternative source for the graft was prompted for a reason peculiar to the Regional Neurological Centre, Newcastle upon Tyne, where a prospective study of the relative merits of the various methods of management of cervical spondylotic myelopathy is in progress (Kalbag, 1972). Serial functional assessment of the patients was one of the basic features in the study, and it was considered that pain from the donor site would introduce a bias by reducing the timed performance figures for the Cloward group.

Commercially produced heterografts have been available for many years but are still viewed with reservation. It was, however, felt that as far as the treatment of degenerative disc disease was concerned, such grafts were worth consideration.

Kiel bone is a processed animal bone prepared from young calves. It was introduced in 1957 (Maatz and Bauermeister, 1957). It is partially deproteinized and according to the authors it is substituted by living bone faster and more completely than any other bone grafts.

Materials and methods

We have used Kiel bone since June 1968 in over 150 patients, but this survey reviews the results in only 65 consecutive cases from 2 to 5 years after the operation, thus giving a follow-up period of at least 2 years. Seventy-three disc spaces were dealt with in these 65 cases, 8 of which required fusion at two levels. There were 55 males and 10 females and 77 per cent of the cases were in the fifth or sixth decade. The operation was carried out using the standard Cloward technique (Cloward, 1958, 1962) with the patient in Halter traction. The drill hole straddling the disc was made with a 12·5-mm drill and the dowel inserted was 15·5 mm in diameter. A closed suction drain was left routinely in the prevertebral space for 24 hours. No collar was provided for postoperative immobilization of the neck. Apart from paraparetic patients who required intensive physiotherapy, patients were discharged home on the fifth day. Check X-rays of the cervical spine were taken the day after operation, at 6 weeks and then at 6-monthly intervals. We attempt to countersink the dowel slightly or make it flush with the bodies. In 9 patients, however, the first postoperative check X-rays showed the dowel to be slightly protruding forwards beyond the anterior surface of the vertebral bodies (*Fig.* 1*a*). Without immobilization in a collar, follow-up X-rays showed normal alignment and stability indistinguishable from that of a more satisfactorily placed dowel (*Fig.* 1*b*, *c*).

Results

Fifty-six (86 per cent) cases showed satisfactory alignment of the spine without abnormal mobility in flexion or extension at the time of final assessment. In 2 cases the dowel had to be removed because of infection, and the remaining 7 cases showed some complications as described below.

Partial absorption of the Kiel bone dowel was noted in 4 patients at 6 weeks' follow-up, but they had no symptoms. All the same, immobilization in a collar was carried out for 3 months.

Partial resorption of the vertebral bodies adjacent to the graft was seen in 3 patients at the end of 6 weeks, but with a collar alone stability and fixation were obtained.

Fracture of adjacent vertebral bodies was not a feature using autografts but occurred in 2 cases while a Kiel bone was being hammered in, when the anterior edge of one of the adjacent vertebrae was chipped off. This complication occurred in patients with some degree of osteoporosis and marked spondylotic changes. The contributory factor was probably the hard consistency of Kiel bone. Perhaps with the extension of the neck, as recommended by Cloward, this complication could have been avoided, but in our series, where a narrow spinal canal and myelopathy were frequent, extension of the neck under general anaesthesia was considered undesirable because of the obvious hazards of such a manœuvre.

---

* Regional Neurological Centre, Newcastle General Hospital, Newcastle upon Tyne.

graft, which with a diameter of 15·5 mm seems too large for easy introduction into a drill hole 12·5 mm in diameter, especially where the spine shows gross osteophyte formation. Taheri and Gueramy (1972) use a 14-mm dowel where only one space is operated upon and a 12-mm dowel if more than one space warrants attention. The former size would seem preferable to the one we have used.

In conclusion we have failed to confirm that any fusion in the true sense occurs with Kiel bone in cervical interbody fusion; nevertheless, we feel that except in fracture dislocation there is no practical disadvantage in its use and that the saving in operation time and morbidity more than counters any objections to its use in the particular context of cervical spondylotic disease.

Fig. 1. *a*, Lateral X-ray of the cervical spine taken immediately after operation shows anterior protrusion of the dowels which is more marked at the upper level (C4/5). However, follow-up X-rays taken (*b*) 8 months and (*c*) 17 months after the operation show alignment and stability indistinguishable from that of a more satisfactorily placed dowel.

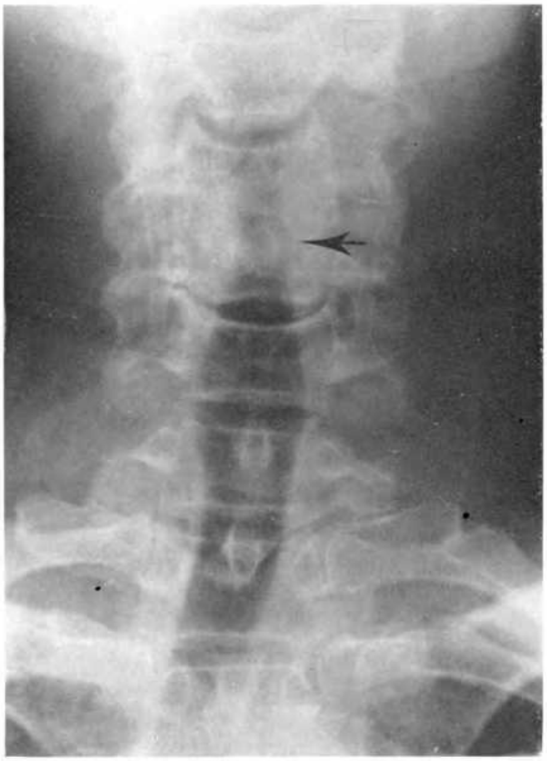

Fig. 2. Anteroposterior X-ray of the cervical spine taken 2 years after operation shows a halo around the dowel.

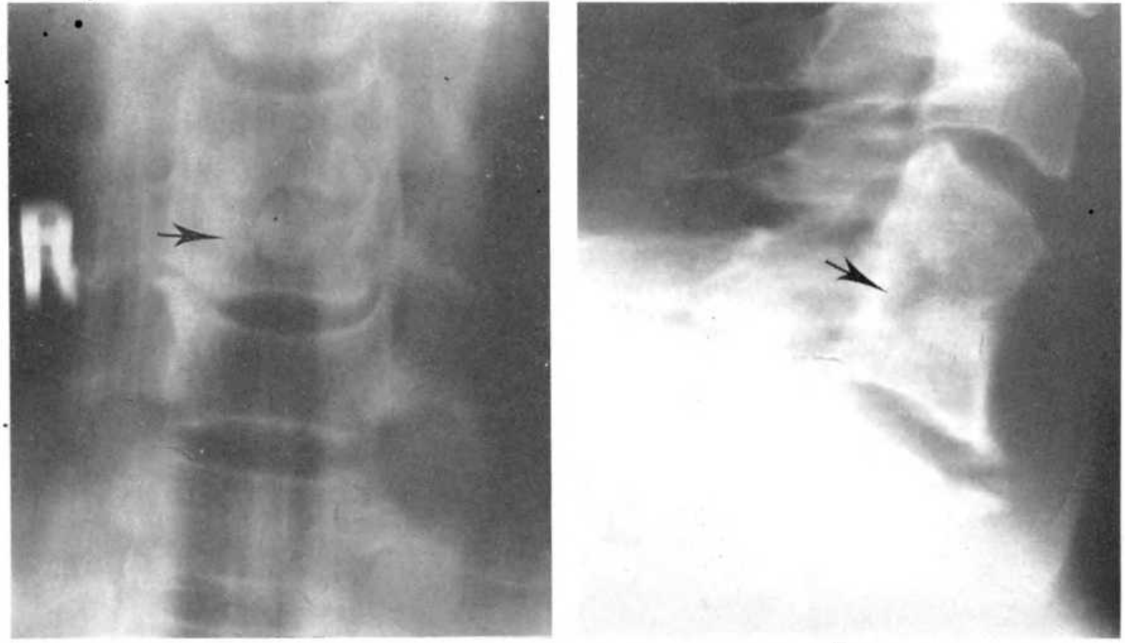

a *b*

Fig. 3. *a*. Anteroposterior tomogram of the cervical spine 2 years after the operation and (*b*) lateral tomogram of the cervical spine nearly 5 years after operation showing a halo around the dowel and indicating the absence of fusion.

All cases with partial absorption of the dowel as well as the adjacent vertebral bodies also showed some later anterior protrusion of the dowel.

In all these 7 cases immobilization in a collar was carried out. The end result was a stable spine although all of them showed some angulation of the spine.

A radiological study of our cases does not show a single case in which one could say with any confidence that bony fusion had occurred. Some patients showed a halo around the dowel (*Fig*. 2) even at the end of 5 years. Those who did not show the halo on plain X-rays were submitted to tomography in two planes and all of them showed a distinct halo surrounding the dowel (*Fig*. 3). We have interpreted this halo as a zone of fibrous tissue encaging the graft. We cannot therefore confirm that fusion occurs with the use of Kiel bone.

Discussion

Cloward (1962), reporting his experience with cadaver bone, thought that the common belief that autologous bone is superior to homologous bone was untenable. Burwell (1969), in a most comprehensive review of the fate of bone grafts, concluded that the best bank bone for clinical use seemed to be the freeze-dried homologous cancellous bone sterilized by irradiation. However, Taheri and Gueramy (1972), reporting on 200 cases with cervical disc disease who were operated on using the Cloward technique, stated that with heterogenous bone the results are good, the operation time is shortened and complications are diminished. They graded their patients radiologically into 'excellent', defined as good fusion and no angulation, while 'good' implied sound fusion but minimal angulation; 85·5 per cent were considered excellent and 11·5 per cent good, indicating that fusion or bony union had occurred in 97 per cent. This compares very favourably with the results quoted by Robinson et al. (1962). Admittedly, like the present series, this was a smaller series of 55 cases in which ileal autografts were used with an approximately 88 per cent fusion rate. A radiological study of our own cases does not show a single case in whom one could say with any confidence that bone fusion had occurred.

However, the absence of true fusion does not show any material disadvantages in the particular situation that we are considering, namely cervical disc disease, where spinal instability such as in fracture dislocation is rare. Our series shows 'satisfactory' results in 86 per cent in that alignment and stability have been achieved without convincing evidence of fusion. As designed for the spine, the Cloward operation using a dowel 3 mm larger than the drill hole provides firm splinting and with the resultant close approximation to a bed of vascular cancellous bone. Even with merely the splinting effect at the site of operation, the aims of the particular procedure are achieved, i.e. (1) removal of the disc and osteophyte, (2) fixation of the spine and (3) distraction of the adjacent vertebral bodies providing increased room in the intervertebral foramina. In this respect the results appear to be superior to those of autografts; Robinson et al. (1962) found abnormal mobility in flexion and extension in 9 out of the 56 patients reported.

Mechanical damage to the adjacent vertebral bodies could be related to the consistency and size of the

Surgical Research Society

A meeting of the Surgical Research Society was held in King's College Hospital, London, on 3 and 4 January 1975 with Professor A. P. M. Forrest (President of the Surgical Research Society) in the chair. The following papers were presented:

1. An *in vivo* test of immune responsiveness in man

J. R. SALAMAN and D. MILLAR, *Institute of Renal Disease, Cardiff Royal Infirmary*

A test has been devised with the object of assaying immune responsiveness in normal and immunodepressed persons and is based on the graft-versus-host model of Ford et al. (1970) and employs rat antigens as the immunological stimuli. Peripheral blood lymphocytes were injected into the hind feet of young Wistar rats; 7 days later the popliteal lymph nodes were removed and weighed. It was found that the unwanted host-versus-graft activity could be suppressed in the rats by total body irradiation, 300 rad being the optimum dose. Inactivated lymphocytes were injected into the right hind foot as a control. Inactivation by irradiation (2400 R) was not completely successful and formolization was found to be a more satisfactory alternative.

In each test formolized and unformolized cells (in the same dose) were injected into the right and left hind feet respectively and the result expressed as a ratio—weight of left node : weight of right node. Lymphocytes from 45 healthy individuals were examined in this way. Experiments were performed in triplicate and the mean ratio plotted against the dose of cells injected. A close linear correlation was found ($r = 0{\cdot}86$) which could be expressed as:

$$\log \text{response} = 0{\cdot}234 + 0{\cdot}741 \log \text{dose} \pm 0{\cdot}538.$$

All normal individuals reacted similarly and a 'poor responder' group could not be identified. However, patients with immune depression could be shown to be statistically distinct.

2. Effect of revisional surgery for vasomotor dumping on kinin release

A. CUSCHIERI, KAREN J. WORTHINGTON and BARBARA MASON, *Department of Surgery, University of Liverpool*

A controlled clinical trial of isoperistaltic versus antiperistaltic jejunal interposition for severe vasomotor dumping is in progress in Liverpool. To date 17 patients have been admitted to the trial. The effect of surgery on kinin release has been studied in patients who were rendered symptom-free by surgery (group A, $n = 11$) and others who were not improved (group B, $n = 6$). Kinin results are expressed in ng/ml as the mean ± standard error.

Each patient was given a hypertonic glucose meal (100 g) before the operation and in all 17 patients a dumping attack was diagnosed. Peripheral venous blood was taken before the attack and at the height of the vasomotor symptoms. The blood was extracted for estimation of the free bradykinin activity (Talamo et al., 1969), which was assayed on the isolated rat uterus. Haematocrit estimations were also performed. The hypertonic glucose test was repeated 3 months after surgery, except that in the patients who did not dump at this stage blood was taken before and 30 minutes after the glucose meal.

The resting preoperative venous kinin was $1{\cdot}89 \pm 0{\cdot}50$ ng/ml in group A patients and $1{\cdot}30 \pm 0{\cdot}35$ ng/ml in group B patients ($P > 0{\cdot}05$). However, this rose to $56{\cdot}15 \pm 11{\cdot}9$ ng/ml after glucose administration in group A cases compared with $3{\cdot}65 \pm 2{\cdot}33$ ng/ml in group B ($P < 0{\cdot}01$). At 3 months after operation the kinin level after a glucose meal was $4{\cdot}18 \pm 1{\cdot}20$ ng/ml in group A. This was significantly lower than the preoperative level in the same group during a dumping attack ($P < 0{\cdot}01$) and similar to the fasting level at 3 months after surgery.

These results indicate that patients labelled as vasomotor dumping syndrome do not form a homogeneous group. Moreover, a preoperative demonstration of kinin release during an attack provoked by hypertonic glucose is indicative of a successful outcome after revisional surgery for the dumping syndrome.

3. Measurement of Po_2 in normal and ischaemic human skin

V. A. SPENCE and W. F. WALKER, *Department of Surgery, Ninewells Hospital, Dundee*

Monitoring of tissue Po_2 may play an important role in estimating the degree of shock and response to therapy. In view of the shortcomings of existing electrodes we developed a micro-electrode suitable for measuring skin Po_2 in man with excellent reproducibility and stability.

The mean skin Po_2 in 15 controls using 71 electrodes was 34 ± 5 mm Hg. A rapid increase to about three times the control value followed oxygen administration, with an equally rapid decline when oxygen was stopped.

The relationship of Po_2 to skin blood flow was determined using ^{133}Xe.

Patients with peripheral vascular disease served as a stable model for shock. The skin Po_2 was measured in the limbs of 20 patients, each acting as his own control. In severe ischaemia the Po_2 was 20 mm Hg or less and the response to oxygen was nil. The response varied with the degree of ischaemia. In the reversible situation Po_2 and skin blood flow improved following operation.

It is concluded that the micro-electrode designed is stable and gives reproducible results; the control Po_2 is a good guide to tissue blood flow; the Po_2 gradients provide valuable information on changes in blood flow and oxygen metabolism; and, finally, the electrode is suitable for studies in shock now in progress.

4. Pregnenolone metabolism as a prognostic guide in human mammary carcinoma

N. J. O'HIGGINS, N. DESHPANDE and PAMELA CARSON (J. L. BOAK), *Department of Surgery, Royal Postgraduate Medical School, and Imperial Cancer Research Fund*

Low plasma concentrations and urinary excretion of androgens may be associated with poor response to endocrine treatment in patients with advanced breast cancer (Brownsey et al., 1972) cortisol levels may also be raised in advanced disease (Jensen et al., 1968).

Pregnenolone is converted to androgen and cortisol. It was considered that the conversion rate of pregnenolone to androgen might be reduced and the conversion rate to cortisol increased in unresponsive patients with advanced mammary cancer.

After a bolus injection of 10 μCi, 40 μCi of tritium-labelled (^{3}H) pregnenolone in saline were infused intravenously for 4 hours through an electrically driven pump. Hourly plasma samples were analysed by paper chromatography for concentrations of radioactive pregnenolone, cortisol and the androgen dehydroepiandrosterone (DHA).

In 45 patients the ratio of DHA to cortisol was similar in those with early and advanced disease. Of 26 patients with advanced disease, the DHA : cortisol ratio was significantly ($P<0{\cdot}01$) lower in the 19 patients who failed to respond to endocrine treatment (mean ratio 0·548) when compared with the 7 who responded favourably (mean ratio 1·1).

ACTH increased the concentration of cortisol and DHA, but did not alter the DHA : cortisol ratio significantly.

Reduced conversion of pregnenolone to DHA probably explains the low androgen levels observed in unresponsive mammary cancer.

5. The relationship between alcohol and head injury and its effect on the conscious level

S. GALBRAITH, W. R. MURRAY, A. R. PATEL and R. KNILL-JONES (W. B. JENNETT), *The University Departments of Surgery, Medicine and Neurosurgery, The Institute of Neurological Sciences, Glasgow, and The Western Infirmary, Glasgow*

Recent intake of alcohol may complicate assessment of the conscious level after head injury and may make it difficult to recognize the development of complications such as intracranial haematoma. Of 200 consecutive traumatic intracranial haematomas, 72 (36 per cent) had been deteriorating for more than 12 hours before being referred to the Department of Neurosurgery; in half of these alcohol was a confusing factor. The extent to which alcohol contributes to the problem of head injuries and their assessment was explored by measuring alcohol levels in 400 consecutive head injuries admitted to general surgery wards. The relationship between the blood alcohol and conscious state was assessed using the Glasgow coma scale (Teasdale and Jennett, 1974).

Recent alcohol consumption was suspected clinically in 224 (56 per cent) of head injuries and in 75 per cent of males over the age of 18 years. In these the mean blood alcohol level was 193 mg per cent (maximum 375 mg per cent). As a cause of injury, road accidents were only marginally more common (108, 27 per cent) than assaults (98, 24·5 per cent) and 'falls under the influence' (92, 23 per cent). Mean alcohol levels were higher for 'falls under the influence' (189 mg per cent) than assaults (121 mg per cent) and road traffic accidents (58 mg per cent). These differences are significant.

Of the patients with recent alcohol intake, 328 (82 per cent) were fully conscious on the coma scale, the mean blood alcohol level being 134 mg per cent. Disorientation was observed in 68 (17 per cent) in whom the mean blood alcohol was 203 mg per cent. These differences are significant. Only 4 could be described as 'in coma', the mean blood alcohol being 326 mg per cent.

These results indicate that many patients with head injury in Glasgow have recently taken considerable quantities of alcohol. The level is related to the way in which the injury occurred, and alcohol is probably an important causative factor. High levels are necessary before the conscious level is affected and coma results only at levels greater than 300 mg per cent.

TEASDALE G. and JENNETT W. B. (1974) Assessment of coma and impaired consciousness. *Lancet* **2**, 81–84.

6. Haemostasis and healing following median sternotomy

T. G. J. BRIGHTMORE (C. WASTELL), *Thoracic Surgical Unit, Westminster Hospital, London*

Following median sternotomy the standard method for securing haemostasis is bone wax. Examination of sterna from 6 patients who died up to 5 years after sternotomy has demonstrated an obstructive effect of the wax on healing.

To find a haemostatic without this adverse effect, median sternotomy was performed on 83 goats. The animals were divided into six groups and sternal blood loss was measured over two 15-minute periods. In each group the haemorrhage was unchecked in the first period. In the second it continued unchecked in the control group (22), but in the other groups haemostasis was attempted with wax (12), collagen (11), isobutyl-cyanoacrylate (15), collagen and isobutyl-cyanoacrylate (12) and an autologous red cell compound devised for this study (11). Sixty-two animals survived. The animals were sacrificed at intervals from 1 day to 6 months. Sternal transverse sections were photographed, X-rayed and examined microscopically. A scoring system based on the microscopy was used to measure sternal healing.

Differences in blood loss per unit sternal area in the first period between groups could not be shown to be significant. In the second period analysis of variance shows that the blood loss per unit area in the control group was significantly higher than in the treated groups (for $F(7;\ 70)$, $P<0{\cdot}001$), but a significant difference between treated groups could not be shown. However, wax and the red cell compound were superior, taking into account ease of application. The obstructive defect in healing with wax was not seen with the autologous red cell compound. The latter is proposed as a sternal haemostatic and its effect on human sterna has been tested in 6 patients with favourable results.

7. Gastro-intestinal hormonal responses following massive small bowel resection

A. A. B. BARROS D'SA, T. L. KENNEDY, K. D. BUCHANAN and T. G. PARKS, *Departments of Surgery and Medicine, The Queen's University and Royal Victoria Hospital, Belfast*

Are humoral mechanisms responsible for hypermotility and gastric hypersecretion which are recognized sequelae of massive small bowel resection?

The effect of a fat meal on circulating gastro-intestinal hormones was assessed in dogs before and after 75 per cent small bowel resection. The following hormones were measured by radio-immunoassay: insulin, gastrin, secretin, total glucagon-like immunoreactivity (GLI) and pancreatic glucagon.

In 9 conscious dogs resection produced significant falls in basal and stimulated levels of total GLI in peripheral venous blood ($P<0{\cdot}05$) and insignificant rises in basal and stimulated gastrin values. Secretin levels fell minimally.

To clarify the source of the GLI further, acute experiments were undertaken with 5 anaesthetized dogs in each of the following groups: (*a*) laparotomy; (*b*) resection; (*c*) resection and total pancreatectomy; (*d*) pancreatectomy.

Following resection alone stimulated gastrin levels rose ($P<0{\cdot}05$), but when resection was combined with pancreatectomy the rise was more sustained ($P<0{\cdot}05$). Pancreatectomy alone was without effect on gastrin secretion.

Resection in anaesthetized dogs confirmed a reduction of total GLI, especially when pancreatectomy was added ($P<0{\cdot}05$). Pancreatectomy alone depleted total GLI by 83·5 per cent ($P<0{\cdot}001$) and pancreatic glucagon by 91 per cent ($P<0{\cdot}001$).

These hormonal abnormalities may be relevant to the pathophysiology of massive small bowel resection and support the concept that an enteric islet cell axis for fats may exist.

8. Highly selective vagotomy for duodenal ulcer: is antrectomy needed for the hypersecretors?

I. R. PICKFORD, D. JOHNSTON, B. E. WALKER and J. C. GOLIGHER, *University Department of Surgery, The General Infirmary, Leeds*

Kronborg (1972) has suggested that duodenal ulcer patients with a maximum acid output (MAO) greater than 46 mEq/hr (M), or 42 mEq/hr (F) should have antrectomy added to vagotomy, because after vagotomy and drainage recurrent ulceration was found in 14 per cent of hypersecretors, but in only 2 per cent of normal secretors. For similar reasons, Robbs et al. (1973) recommended vagotomy and antrectomy for duodenal ulcer patients with MAO > 25 mEq/hr.

Since highly selective vagotomy (HSV) is even more conservative than vagotomy and drainage we were interested to find out whether 'hypersecretors' (peak acid output > 50 (M) and > 40 (F) mEq/hr) had worse clinical results after HSV than 'normal secretors'. Results in 40 hypersecretors were compared with those of 60 normal secretors 2–6 years after HSV. Mean ages (42 years), and the incidence of incomplete vagotomy (6 per cent) were equal in the two groups.

Results for hypersecretors compared with normal secretors were: Visick grades 1+2, 85 per cent versus 88 per cent; proved recurrent ulcer, both 0 per cent; ulcer-type pain (often transient), both 7 per cent; diarrhoea, both 4 per cent; early dumping, 1 per cent versus 7 per cent ($P = 0{\cdot}054$); other symptoms, no significant difference.

These results suggest that HSV is adequate surgical treatment for patients who have duodenal ulcer and very high acid output. Antrectomy does not seem to be necessary, provided that the incidence of incomplete vagotomy can be kept low.

ROBBS J. V., BANK S., MARKS I. N. and LOUW J. H. (1973) Selection of operation for duodenal ulcer based on acid secretory studies: a reappraisal. *Br. J. Surg.* **60**, 601–605.

9. Glucose tolerance and insulin secretion after selective gastric vagotomy and pyloroplasty

R. BITTNER, H. G. BEGER, E. KRAAS and R. ROSCHER, *Department of Surgery, Klinikum Charlottenburg, Free University, Berlin*

Hyperglycaemia following oral glucose load in patients after truncal vagotomy and pyloroplasty is well documented (Thomford et al., 1974). The influence of selective gastric vagotomy and pyloroplasty (SGV+P) on glucose tolerance and insulin secretion remains unclear.

In the early postoperative period (days 6–10) 19 glucose infusion tests (GIT) and 16 oral glucose tests (OGT) were performed in 10 patients after SGV+P and in 12 control patients after abdominal surgery. To obtain more precise information blood samples were taken simultaneously from the portal vein and one cubital vein (Bittner et al., 1973).

The mean disappearance rate of glucose (k value) as well as the pattern and area below the insulin concentration curve (ΔIRI) are nearly identical in both test groups (SGV+P: $k = 0{\cdot}94$, ΔIRI (portal vein) = 18 702·5; control: $k = 1{\cdot}02$, ΔIRI (portal vein) = 18 401).

Glucose (mg/100 ml)

	Fasting	60 min	120 min	180 min
SGV+P*	74 ± 9	130 ± 31	107 ± 19	92 ± 12
Control*	86 ± 13	171 ± 43	162 ± 50	132 ± 42
	$P < 0{\cdot}05$	$P < 0{\cdot}025$	$P < 0{\cdot}01$	$P < 0{\cdot}025$

Insulin (μu./ml portal vein)

	Fasting	30 min	60 min	90 min	150 min
SGV+P*	37 ± 36	113 ± 63	79 ± 52	53 ± 26	36 ± 16
Control*	27 ± 15	49 ± 22	82 ± 46	103 ± 46	86 ± 56
	NS	$P < 0{\cdot}01$	NS	$P < 0{\cdot}01$	$P < 0{\cdot}025$

* $n = 8$. NS, No significance.
Insulin levels in the cubital vein showed no significant differences.

In patients with SGV+P the responsiveness of the β-cells to glucose stimulation is not altered. In addition, the oral glucose tolerance is more nearly normal compared with the control patients. The peak concentration of insulin is reached more rapidly. These results lead to the conclusion that in man after an oral glucose load SGV+P intensely provokes the release of an intestinal factor which is a potent stimulator of insulin secretion.

10. Effect of proximal gastric vagotomy and total vagotomy on the co-ordination of electrical activity of the stomach and duodenum

P. AEBERHARD and B. S. BEDI, *Department of Surgery, Western Infirmary, Glasgow*

Gastric retention occurs following total vagotomy alone. One of the reasons for this retention may be the lack of co-ordination of the motor activity between the stomach and duodenum. As electrical activity can be used to monitor the motor activity of the gastro-intestinal tract, experiments were designed to study the effect of proximal gastric vagotomy (PGV) and total vagotomy (TV) on the co-ordination of the electrical activity across the gastroduodenal area.

The electrical activities from the antrum and duodenum were recorded using monopolar silver–silver chloride electrodes in 4 fully conscious mongrel dogs. The recordings were made after ingestion of a meat meal. After a control study PGV was performed and the recordings repeated. Approximately 8 weeks later, total vagotomy was carried out and the records made. A method of cross-correlation was applied to the electrical recordings obtained before and after the vagotomy.

The relationship between the antral pacesetter potential and the occurrence of duodenal action potentials was observed in the control studies and this co-ordination persisted following PGV and TV.

The results of this study suggest that PGV and TV have no effect on the co-ordination of the motor activity of the stomach and duodenum.

11. A dumping provocation test

C. LAWSON-SMITH and J. P. S. THOMSON (M. HOBSLEY), *Department of Surgical Studies, The Middlesex Hospital, London*

The dumping syndrome is a common sequela to gastric surgery. In most patients it is readily diagnosed, but there are exceptions. Our findings with a test designed to provide an objective diagnosis of dumping are reported.

The fasting patient, lying semi-recumbent, drank 200 ml 50 per cent glucose. Symptoms were noted and the plasma volume fall estimated from serial haematocrit measurements (Le Quesne et al., 1960).

One hundred and twenty-five patients were studied after operations for peptic ulceration (partial gastrectomy 33, truncal vagotomy 43, selective vagotomy 31, proximal gastric vagotomy 18).

The patients fell into three *clinical* groups:

1. Asymptomatic (54). Of these, 40 experienced no symptoms during the test.
2. 'Dumpers' (63). All had dumping symptoms during the test.
3. Those with abdominal pain suggestive of recurrent ulceration (8). Six experienced their pain during the test and had a large plasma volume fall (15·5 ± 1·4 (s.e.m.) per cent), thereby establishing a diagnosis of dumping. The other 2 were asymptomatic during the test and a recurrent ulcer was later confirmed in both.

Thirty-four of the 42 patients who were asymptomatic during the test had a plasma volume fall of less than 9 per cent, whilst 79 of the 83 patients with dumping symptoms during the test had a fall of 9 per cent or more.

This test provided objective evidence of dumping, and it is of value in assessing patients with symptoms after gastric surgery.

LE QUESNE L. P., HOBSLEY M. and HAND B. H. (1960) The dumping syndrome—1. Factors responsible for the symptoms. *Br. Med. J.* **1**, 141–147.

12. The coexistence of dumping and duodenogastric reflux

I. A. DONOVAN, M. R. B. KEIGHLEY, D. W. GRIFFIN, L. K. HARDING and J. ALEXANDER-WILLIAMS, *The General Hospital and Dudley Road Hospital, Birmingham*

The symptomatic sequelae induced by gastric operations are notoriously complex. They are usually associated with gastric retention, early rapid passive gastric emptying (cascading or gastric incontinence) or duodenogastric reflux. First impressions would suggest that cascading and reflux would not occur together; however, clinical experience suggests that they may.

In a prospective randomized trial 20 patients with duodenal ulceration were studied before operation and 9 after proximal gastric vagotomy (PGV) and 11 after truncal vagotomy and antrectomy (TV+A). Emptying of solid and liquid meals was measured by γ scintiscanning (^{113}In). Reflux was studied radiologically (Capper et al., 1966) and by measuring bile pigment concentrations in residual and basal gastric aspirate.

After PGV 3 patients cascaded liquids and 1 had reflux. None had both abnormalities. After TV+A, 9 patients cascaded liquids and 6 had reflux. Five both cascaded and refluxed. Furthermore, in 3 of these 5 patients delayed active emptying was also present ($T_{\frac{1}{2}}>80$ minutes).

Therefore, bile reflux does occur in patients who cascade, and the refluxed bile may remain in contact with the gastric mucosa for a long time. These findings emphasize the importance of the antropyloric mechanism as a two-way sphincter.

CAPPER W. M., AIRTH G. R. and KILBY J. O. (1966) A test for pyloric regurgitation. *Lancet* 2, 621–623.

13. Duodenal ulceration, gastric emptying, enteroglucagon release and abnormal oral glucose tolerance

C. LAWSON-SMITH, D. N. L. RALPHS, S. BLOOM and M. HOBSLEY, *Department of Surgical Studies, The Middlesex Hospital, London*

The greater rise in blood glucose produced by oral glucose in duodenal ulcer patients compared with controls (Humphrey et al., 1972) has been variously attributed to differences in rates of gastric emptying or enteroglucagon release. These possibilities have been investigated in 10 controls and 17 duodenal ulcer patients by measuring the half-life ($T_{\frac{1}{2}}$) of emptying of 200 ml 50 per cent glucose labelled with ^{113}In and estimating plasma enteroglucagon and blood glucose at intervals for 2 hours.

The rise in blood glucose concentration (106·8±6·6 (s.e.m.) mg/100 ml) in duodenal ulcer patients was greater ($t=3{\cdot}942$, $P<0{\cdot}001$) than in the controls (64·6±8·3 mg/100 ml). There were significant correlations between log $T_{\frac{1}{2}}$ and (*a*) the rise in blood glucose concentration ($r=0{\cdot}491$, $P<0{\cdot}05$) and (*b*) enteroglucagon release (Spearman's rho, $r_S=0{\cdot}4429$, $P<0{\cdot}05$). However, enteroglucagon release *did not* correlate with blood glucose. After the blood glucose increases were standardized for different rates of gastric emptying, the rise in blood sugar in the DU group (99·4±8·6 mg/100 ml) remained significantly greater ($t=3{\cdot}358$, $P<0{\cdot}005$) than in the controls (65·9±5·1 mg/100 ml).

It is concluded that the shape of the glucose tolerance curve in duodenal ulcer patients compared with controls is not related to enteroglucagon release and only partly to stomach emptying. The cause of the greater rise in blood glucose in duodenal ulcer patients has yet to be elucidated.

HUMPHREY C. S., DYKES J. R. W. and JOHNSTON D. (1972) Glucose tolerance and insulin secretion in patients with chronic duodenal ulcer. *Br. Med. J.* 4, 393–396.

14. The slowing of gastric emptying by intestinal hormones

M. MEVES, H. G. BEGER, U. HAUBOLD and B. HÜTHWOHL, *Departments of Radiology and Surgery, Klinikum Charlottenburg, Free University, Berlin*

The influence of gastro-intestinal hormones on motor function of the stomach in man has been clearly established. This investigation has been performed in 33 healthy volunteers to determine the alteration of the gastric emptying process by a 20-minute infusion of natural hog gastrin I (2 μg/kg body weight) or pentagastrin (6 μg/kg body weight) or GIH-secretin (75 u.) or glucagon (Lilly, 1 mg).

Gastric emptying was measured by a modification of the scintiscan technique (Griffith et al., 1966), using a ^{51}Cr-labelled semi-solid test meal. The hormones were infused intravenously with a constant speed during a 20-minute period (period II). The alteration of the emptying process compared with the emptying before (period I) and after (period III) the drug infusion represents the effect of the infused drug on gastric emptying. Therefore the patients served as their own controls.

	Percentage of emptying of test meal during period			
	I	II	III	Student's *t*-test (periods I and II)
Gastrin I	20·1	2·8	10·7	$P<0{\cdot}0025$
	±9·5	±2·1	±6·6	
Pentagastrin	20·5	2·2	9·9	$P<0{\cdot}0025$
	±10·5	±2·6	±7·5	
GIH-secretin	25·2	3·4	18·0	$P<0{\cdot}0001$
	±6·6	±3·2	±2·5	
Glucagon	19·8	0·7	11·7	$P<0{\cdot}0001$
	±9·2	±0·5	±7·5	

Although gastrin and pentagastrin stimulate antral motor activity, both slow the gastric emptying of ordinary food to a significant degree ($P<0{\cdot}0025$), probably by increasing the intraduodenal pressure. Secretin and glucagon were found to slow gastric emptying significantly ($P<0{\cdot}0001$), probably by inhibiting antral motor activity.

15. Immunological status of rats with passively enhanced renal allografts

P. J. MORRIS (H. A. F. DUDLEY), *Nuffield Department of Surgery, University of Oxford, Radcliffe Infirmary*

The administration of DA anti-Lewis serum to DA rats at the time of transplantation of (DA×Lewis)F_1 renal allografts prevents rejection and results in indefinite survival of all animals (Fabre and Morris, 1972, 1973). The following experiments were designed to elucidate the mechanism of immunosuppression in these animals with long surviving grafts.

1. In DA recipients intravenous injection of 3×10^8 lymph node and spleen lymphocytes 32 weeks after transplantation did not result in rejection of the renal allograft.

2. DA serum from long surviving animals did not block the response of normal DA lymphocytes to (DA×L)F_1 lymphocytes in mixed lymphocyte culture (MLC), although known enhancing sera did.

3. DA lymphocytes from long surviving animals showed some diminution in response to (DA×L)F_1 lymphocytes in MLC.

4. Eight weeks after transplantation of (DA×L)F_1 kidney into 6 enhanced DA recipients with one of its own kidneys remaining, the (DA×L)F_1 kidney was removed. The animal's remaining kidney was removed 2, 4 or 8 weeks later and replaced with a new (DA×L)F_1 kidney (2 animals in each group). The new kidney was not rejected, all the animals surviving indefinitely.

These findings indicate that the continuing survival of passively enhanced renal allografts in this model is not due to blocking factors, and is better explained on the basis of specific clonal deletion or inactivation.

16. Nature of cells removed from rejecting rat cardiac allografts

S. G. MACPHERSON, N. L. TILNEY, T. B. STROM and C. B. CARPENTER (D. N. H. HAMILTON), *Department of Surgery, Western Infirmary, Glasgow, and Departments of Medicine and Surgery, Harvard Medical School, Boston, Massachusetts, USA*

Cells infiltrating rat cardiac allografts have been studied *in vitro* with respect to their morphology and surface properties.

One hundred and six heterotopic heart transplants (Ono and Lindsey, 1969) were performed using BN or LBNF$_1$ rats as donors to Lewis recipients. Rejection, as measured by cessation of palpable beat, occurred at 7–9 days. The allografts were removed 3–8 days following transplantation and were diced, passed through a mesh, incubated with DNAase and the cells separated with Ficoll-Hypaque.

B cells with surface immunoglobulin were identified by fluorescein-labelled rabbit anti-rat IgG and comprised 47 per cent of the yield at days 3–4 and 35 per cent at days 5–6. At 3–4 days 43 per cent of cells had a surface receptor for the Fc fragment of immunoglobulin; 0·3 per cent of the harvested cells bound the C$_3$ component of complement and formed EAC rosettes.

Macrophages were identified using acridine orange stain and formed 14–24 per cent of the cell population.

T lymphocyte function was demonstrated in a lymphocyte-mediated cytotoxicity test using ^{51}Cr-labelled donor cells as targets. Lysis peaked at 33 per cent at day 4–5. It is presumed that the T cells constitute the 29–48 per cent of the population not previously identified.

T lymphocytes and macrophages therefore invade the rat cardiac allograft during rejection, but there is also a population of B lymphocytes, unusual in that they lack C$_3$ surface receptors.

17. Should preserved organs be continuously perfused?

L. S. AGRAWAL, I. L. ROSENBERG and G. R. GILES, *University Department of Surgery, St James's Hospital, Leeds*

The optimal conditions for organ perfusion are still uncertain, particularly in respect to perfusate constituents and perfusion dynamics. We have used the rat heart preservation model described by Calman and Bell (1972) to investigate and compare four perfusates in an attempt to preserve the hearts for 24 hours. The four solutions used were: K solution with Dextran (Calman and Bell, 1972), K solution with PPF, K solution with 4 per cent Ficoll and Tyrode's solution with 4 per cent Ficoll.

It did not prove possible to preserve hearts for 24 hours using a simple flush and storage at 4 °C with K solution containing either Dextran or PPF. However, 50 per cent of the hearts were preserved in this manner by K solution or Tyrode's solution with Ficoll. Each solution was then tested in four programmes of perfusion with groups of 10 hearts. Continuous perfusion for 24 hours did not preserve any of the 40 hearts tested and all hearts were grossly oedematous.

Intermittent perfusion was tested by: (*a*) perfusion of each heart for 2 minutes every hour (8 of 40 hearts preserved); (*b*) perfusion for 2 minutes every 2 hours (17 hearts preserved); (*c*) perfusion for 2 minutes every 6 hours (23 hearts preserved). In the last group 80 per cent of hearts preserved in Tyrode's solution with Ficoll and all 10 hearts preserved in K solution with Ficoll were successfully resuscitated.

The results suggest, for this animal model at least, that there does not seem to be any advantage in continuous perfusion and that intermittent flushing of the organ at infrequent intervals gives better results.

18. Preservation of isolated pancreatic islets

J. FERGUSON, R. H. ALLSOPP, R. M. R. TAYLOR, I. D. A. JOHNSTON and F. LATIMER, *Department of Surgery, University of Newcastle upon Tyne*

Isolated pancreatic islets have been successfully transplanted to the testis and omentum in guinea-pigs (Ferguson and Scothorne, 1972). If islet cell transplantation has any part to play in the surgical management of diabetes mellitus, methods of harvesting and preservation need further study.

This report describes the histological changes associated with three methods of preservation: (*a*) simple cold storage in Hanks balanced salt solution at 4 °C; (*b*) organ culture of microdissected islets; (*c*) storage of islets in liquid nitrogen at −187 °C.

Isolated islets were obtained using a free-hand microdissection procedure. The islets were studied by light microscopy after staining with Gomoris's aldehyde fuchsin stain.

Forty per cent of islets stored at 4 °C for 24 hours showed histologically viable alpha and beta cells. At 48 hours approximately 10 per cent showed viable cells. At 72 hours all islets were necrotic.

Microdissected islets from mouse, rat and guinea-pig were successfully cultured for up to 28 days.

Histologically recognizable alpha and beta cells have been observed following 24 hours' storage at −187 °C.

Organ culture is a satisfactory method for the long term preservation of isolated pancreatic islets. In a few cases histological evidence of survival has been correlated with functional studies.

FERGUSON J. and SCOTHORNE R. J. (1972) Transplantation of the endocrine pancreas in guinea pigs. *Br. J. Surg.* 59, 316.

19. Perfusate lactic acidosis in the assessment of human cadaver kidneys

R. W. G. JOHNSON, R. M. R. TAYLOR, J. SWINNEY and F. O. BELZER, *Departments of Surgery, University of Newcastle upon Tyne, and University of California, USA*

Perfusion characteristics alone do not adequately measure pre-existing damage in human cadaver kidneys, especially those that have been stored on ice before perfusion.

In this study 112 human cadaver kidneys arriving at two transplant centres were assessed by measuring the accumulation of lactic acid in the perfusate during the first hour of continuous perfusion. Lactate was measured on a Boehringer ultraviolet test kit and expressed in mg/100 ml corrected to a perfusate volume of 400 ml.

Storage method	IF	MLC	DF	MLC	NF
Perfusion*	55	29·6±5	13	60·2±6	0
+ ice, perfusion†	11		30		3
Total	66		43		3

IF, immediate function; MLC, mean lactate concentration (mg %); DF, delayed function; NF, non-function.
* $n = 58$. † $n = 44$.
Range of lactate concentration (mg %):
Perfusion alone: nil.
Perfusion+ice perfusion: 70>100.

Sixty-eight kidneys were stored on perfusion alone. The mean duration of storage was 28±6 hours. Immediate function rate was 80 per cent.

Forty-four kidneys were stored initially in ice for up to 12 hours and then perfused. The mean total storage time in this group was 25±9 hours. Immediate function rate was 25 per cent and there was a 6 per cent primary non-function rate.

There was a highly significant difference in perfusate lactic acidosis between the kidneys which functioned immediately and those in which onset of function was delayed; the mean difference was 30·6 mg per cent ($t = 12\cdot9$, $P < 0\cdot001$). The lactate concentrations for the 3 non-functioning kidneys ranged from 70 to >100 mg per cent.

Measurement of perfusate lactic acidosis when taken in conjunction with perfusion characteristics will accurately predict pre-existing injury in human cadaver kidneys.

20. Evidence of gentamicin nephrotoxicity in patients with renal allografts

J. M. WELLWOOD, A. E. THOMPSON and J. R. TIGHE, *St Thomas's Hospital, London*

Using the sensitive fluorimetric technique for assay of urinary N-acetyl glucosaminidase (NAG) and beta-galactosidase (GAL), elevated enzyme levels have been demonstrated in patients with renal disease (Dance et al., 1970) and during the rejection of renal allografts (Wellwood et al., 1973). We observed striking elevations in urinary enzymes when patients with renal grafts were treated with gentamicin.

Male Wistar rats were kept in metabolic cages. Clean 24-hour urine specimens were collected daily. Differing doses of gentamicin were administered daily for differing periods of time. Elevations in urinary NAG and GAL and histological and ultrastructural changes in rat kidneys were caused when gentamicin was administered in human therapeutic doses.

Urinary enzymes became elevated between 1 and 3 days after the onset of 20 courses of gentamicin in 18 patients with renal allografts. Levels fell between 2 and 5 days after cessation of gentamicin.

The serum creatinine rose during 75 per cent of the courses and urinary protein increased during 65 per cent of the courses. The renal histological and ultrastructural changes induced by gentamicin in rats were found in human renal tissue.

The administration of gentamicin may cause a reduction in function of renal allografts.

21. The action of subcutaneous and intravenous *Corynebacterium parvum* on the 'lymphocyte trap'

D. N. H. HAMILTON and ELISABETH BRADY, *Department of Surgery, Western Infirmary, Glasgow*

Corynebacterium parvum, a potent anti-tumour agent, powerfully attracts lymphocytes to the lymph nodes draining its site of subcutaneous injection. This activation of the 'lymphocyte trap' has been suggested to be the mechanism by which *C. parvum* acts against experimental tumours (Frost and Lance, 1973).

To test this hypothesis *C. parvum* was injected intravenously or subcutaneously into the foreleg of CBA mice, and tumours were then induced in the muscle of the same foreleg with Moloney sarcoma virus (MSV). Syngeneic lymphocytes labelled with ^{51}Cr were then injected intravenously at regular intervals after tumour induction, and as expected subcutaneous *C. parvum* produced a fourfold increase in the lymphocytes migrating to the draining lymph node. Subcutaneous *C. parvum*, however, produced only a 26 per cent reduction in the incidence of the MSV tumours. Intravenous *C. parvum* produced no change in the migration of lymphocytes to the node draining the tumour, but completely prevented the appearance of tumours.

By studying these two routes of administration, the anti-tumour activity of *C. parvum* is only seen with the intravenous route and its stimulation of the trap only with the subcutaneous route. Thus, *C. parvum* does not act on tumours via the 'lymphocyte trap'.

22. Combined surgery and *Corynebacterium parvum* for treatment of a metastasizing tumour in mice

J. E. CASTRO and TESSA E. SADLER, *Urological Unit, Department of Surgery, Royal Postgraduate Medical School, London*

The effects of *Corynebacterium parvum* on the primary Lewis lung carcinoma and its metastases were studied in female C57/BL mice.

When intravenous or intraperitoneal *C. parvum* was given at the same time as subcutaneous inoculation of tumour there was significant reduction in the primary tumour mass and number of pulmonary metastases detected by the methods described by Wexler (1966). Contralateral subcutaneous *C. parvum* had no effects on either the primary tumour or its metastases.

Pulmonary metastases were not observed 10 days after tumour inoculation, but despite excision of the primary tumour at that time pulmonary metastases were consistently found at 21 days.

The combined effects of surgical excision of the primary tumour at day 10 and intravenous injection of *C. parvum* on pulmonary metastases were studied. When surgery and injection of *C. parvum* were on the same day there was only minimal protection, but if *C. parvum* was given one or more days before tumour excision there was protection; indeed, some mice were permanently cured of tumour.

These results suggest that in defined conditions *C. parvum* can prevent pulmonary metastases from the Lewis tumour and it may be useful adjuvant therapy for tumours that have poor prognosis after surgery alone.

23. The relationship between gastro-oesophageal sphincter pressure and gastro-intestinal hormone stimulation

C. H. CALVERT, T. G. PARKS and K. D. BUCHANAN, *Departments of Surgery and Medicine, Queen's University, Belfast*

It has been postulated that the basal gastro-oesophageal sphincter pressure is regulated by plasma gastrin concentration (Lipshutz et al., 1972) and that the pressure increase after alkali and protein is due to gastrin release (Castell and Harris, 1970).

Gastro-oesophageal sphincter pressure was monitored in 40 fasting healthy volunteers for 20 minutes before and 2 hours after an alkali, protein or fat meal. Blood samples were taken for gastrin, secretin, total glucagon-like immunoreactivity (GLI) and pancreatic glucagon radio-immunoassays.

Basal sphincter pressures and basal plasma gastrin concentrations did not show any correlation. After alkali, sphincter pressure increased significantly ($P < 0\cdot01$), but plasma gastrin concentration showed no increase. With protein, sphincter pressure increased significantly ($P < 0\cdot01$) and plasma gastrin concentration also increased significantly ($P < 0\cdot001$). However, the gastrin rise occurred in the first hour whereas the pressure rise lasted 2 hours. Sphincter pressure fell significantly with fat ($P < 0\cdot001$), but plasma glucagon and total GLI did not show a significant rise. Secretin concentration fell transiently after protein stimulation.

This study, with the lack of correlation between gastro-oesophageal sphincter pressures and hormone concentrations, both in the basal and stimulated state, does not support the above hypotheses.

24. Observations of gastric mucosal blood flow using ^{99}Tc in rat and man

T. V. TAYLOR, B. R. PULLAN, J. B. ELDER and B. TORRANCE, *Manchester Royal Infirmary*

The standard method for measuring gastric mucosal blood flow (GMBF) experimentally is aminopyrine clearance (Jacobsen et al., 1966). Using the clearance principle and the criteria of Smith (1951) and Pitts (1966) we have compared GMBF in three groups of 8 rats, each receiving one of the following isotopes: (1) ^{14}C-labelled aminopyrine, (2) tritiated quinine or (3) ^{99}Tc. Under halothane anaesthesia the basal flows were: *0·023±0·006, 0·022±0·005* and *0·0196±0·004 ml/min for these* agents respectively.

As ^{99}Tc is non-toxic and gives results comparable to agents used in the experimental animal, a preliminary study has been made in man.

In 10 fasting conscious patients (7 duodenal ulcer, 2 gastric ulcer and 1 Polya gastrectomy) 1 mCi Tc was given intravenously, and gastric secretion and venous blood samples were collected at 15-minute intervals. After four basal collections, pentagastrin (6 µg/kg) was given intramuscularly and collections continued for a further 60 minutes. Aliquots of gastric juice and venous blood were counted in a Panax scintillation counter, and acid output was also determined.

Mean fasting GMBF was 31·6 ml/min for duodenal ulcer patients, 11·4 ml/min for gastric ulcer patients and 3·4 ml/min following a Polya gastrectomy. After pentagastrin the GMBF increased by 100–250 per cent in all the duodenal ulcer patients.

These results suggest that ^{99}Tc is a suitable agent for the measurement of GMBF in the conscious human subject.

25. Secretagogue-produced duodenal ulcers in the rat and their prevention by the gastric secretory inhibitor UK 9040

S. N. JOFFE, R. GASKIN, A. A. J. BARROS D'SA, A. A. MELO, R. J. N. GRIBBLE, D. P. GIRVAN and J. H. BARON, *Department of Surgery, Royal Postgraduate Medical School, London*

Animal models of peptic ulcers may help us to understand the natural history and treatment of this disease. Of the various methods used to produce duodenal ulcers in animals, one of the nearest to the clinical situation is the production of gastric hypersecretion by infusing secretagogues (Robert et al., 1971).

In the present study pentagastrin (2 or 4 µg/kg min^{-1}) with carbachol (0·4 or 0·8 µg/kg min^{-1}) were infused subcutaneously into rats for 6–48 hours. In each group of 30 rats the duodenal ulceration was expressed as follows: the 'duodenal ulcer index', which is the sum of one-tenth of the percentage incidence of ulcers; severity of ulcer (graded 0 to 5+); and the number of ulcers per duodenum. With increasing duration of infusion and increasing doses of pentagastrin and carbachol there was an increase in the incidence, severity, number, duodenal ulcer index score, caudad distribution, perforation and deaths from peritonitis. With pentagastrin (4 µg/kg min^{-1}) and carbachol (0·8 µg/kg min^{-1}) for 24 hours, every rat developed a duodenal ulcer of 5+ severity, with a mean of 3 ulcers per animal and a 7 per cent mortality from perforation. Control rats infused with saline did not develop any mucosal changes in the stomach or duodenum.

With this satisfactory duodenal ulcer model the gastric secretory inhibitor, UK 9040, an analogue of the antihistamine triprolidine (Hamer et al., 1972), was given orally, 10–100 mg/kg, 1 hour before and at various times during infusion of the secretagogues. The higher the dose and the more frequent the dosage, the lower was the incidence, severity, number and perforations of duodenal ulcers. For example, 100 mg/kg of UK 9040 before infusion completely inhibited the formation of duodenal ulcers in two-thirds of the rats and the ulcers were fewer and less severe.

26. The interpretation of plasma gastrin results—an explanation

R. C. G. RUSSELL, S. R. BLOOM and SHEILA JONES, *Surgical Unit, St Mary's Hospital Medical School, London*

The results of radio-immunoassay of plasma gastrin levels in the basal state vary widely (Hansky and Korman, 1973). Two factors may be responsible: first, different antibodies used by different workers; secondly, the specificity of antibody for big (BG) and little (LG) gastrin. The latter will determine the absolute basal level in that BG predominates in the fasting state and LG in the stimulated phase (Yalow and Berson, 1971).

We report here the cross-reactivity of three antibodies (Gas 8, Gas 9 and RCS 8) for BG and LG, and the values for basal plasma gastrin in 10 normal, 15 duodenal ulcer and 6 post-surgical patients. We have also studied the 6 post-surgical patients after stimulation by a standard meal.

The cross-reactivity for BG was Gas 8, Gas 9, 45 per cent; RCS 8, 68 per cent. Basal plasma gastrin was similar for Gas 8 and 9 but high for RCS 8. The values for incremental response showed no differences. These results suggest that the basal plasma gastrin level is higher the greater the cross-reactivity with BG, and confirms that after a meal the rise is mainly due to LG. Plasma gastrin results cannot be interpreted without knowing the component of gastrin being measured.

Antibody	Normal subjects (pg/ml)	Duodenal ulcer patients (pg/ml)	Meal stimulus Gastrin response (ng)	Meal stimulus Incremental response (ng)
Gas 8	13·7±1·0	18·0±2·0	8·3±1·5	3·8±0·7
Gas 9	13·9±0·6	17·6±1·4	8·1±1·1	3·1±0·5
RCS 8	28·1±3·1	29·6±2·8	12·5±2·1	3·1±0·6

27. Salbutamol: effect on acid secretion and plasma gastrin in human subjects

L. P. FIELDING, J. R. KILBORN and R. C. G. RUSSELL, *Surgical Unit, St Mary's Hospital Medical School, London*

Salbutamol, a β_2 adrenergic stimulant, reduces both pentagastrin- and food-stimulated gastric acid secretion in the dog. These changes are similar to those found with metiamide (Fielding et al., 1974). We have studied the effect of salbutamol on acid secretion and plasma gastrin in human volunteers.

Four subjects were studied twice; placebo or salbutamol 8-mg tablets were taken 2 hours before measurement of basal acid output. Pentagastrin infusion (10 µg/kg hr^{-1}) followed for a 2-hour period.

Mean basal acid output was reduced (3·8–1·0 mEq/hr) as was stimulated acid output in the first and second hours (first hour 16·5–5·4 mEq/hr; second hour 18·1–8·9 mEq/hr).

Seven male subjects had an 'English' breakfast test on four occasions twice preceded by a placebo tablet and twice by a salbutamol 4-mg tablet. Blood samples were taken at 15-minute intervals for 3½ hours and plasma gastrin concentrations measured by radio-immunoassay.

The group means ±s.e.m. for basal and peak plasma gastrin concentrations and integrated gastrin response (IGR) were similar.

	Placebo	Salbutamol
Basal plasma gastrin (pg/ml)	15·6±4·1	109±2·1
Peak plasma gastrin (pg/ml)	32·9±3·1	33·5±3·2
IGR (ng/2 hr)	2978·3±347·1	2969·1±325·9

Thus, salbutamol effectively reduces basal and stimulated acid secretion and does not evoke hypergastrinaemia. These results suggest that salbutamol, like metiamide, has an action both on the acid-secreting cell complex and on the antral gastrin-producing cell.

FIELDING L. P., CURWAIN B. P., RUSSELL R. C. G. and BLOOM S. R. (1974) Evidence for separate actions of an adrenergic β_2 stimulant and a histamine H_2 blocker on the oxyntic and gastrin cells. *Br. J. Surg.* 61, 914.

28. The interaction of cholinergic and histaminic blockades on the parietal cell: therapeutic possibilities

M. H. THOMPSON, MARGITTA ALBINUS, E. L. BLAIR, J. D. REED and C. W. VENABLES, *Departments of Physiology and Surgery, University of Newcastle upon Tyne*

The blockade of histamine H_2 receptors offers new possibilities in the treatment of peptic ulcer disease, and although ulcers heal in the majority of cases, we find that not all patients respond completely to this therapy.

The possibility that there exists a cholinergic pathway controlling part of the gastric acid secretory response separate from that controlled by the histamine-sensitive receptors was investigated in conscious gastric fistula cats. This was done by comparing the inhibition produced by two doses each of metiamide and atropine, used separately and in combination, of maximal pentagastrin-stimulated acid secretion.

The results appear in the table.

	No atropine	Atropine 2 μg/kg	Atropine 100 μg/kg
No metiamide		11·5 ±7·8	40·5 ±6·1
Metiamide 1 mg/kg	8·2 ±9·0	30·4 ±3·4	44·4 ±3·8
Metiamide 5 mg/kg	58·5 ±7·1	71·8 ±1·8	90·2 ±2·2

Results are expressed as percentage mean inhibition ±1 s.e.m.; $n = 6$ in each test.

These data suggest that therapeutic combinations of H_2 and anticholinergics might be beneficial in circumstances where the same dose of either agent would be ineffective.

The additive nature of the inhibition produced by the combination of these two drugs suggests that histaminic and cholinergic pathways, at least in the cat, act separately on the parietal cell and do not interact with each other.

29. The effect of haemorrhagic shock upon plasma glucose, insulin and cyclic AMP levels in the pig

K. PRUDHOE, P. D. WRIGHT, A. L. LATNER and I. D. A. JOHNSTON, *Departments of Surgery and Clinical Biochemistry, University of Newcastle upon Tyne*

Glucose intolerance following injury has been recognized for many years. No single hormone has been shown to be responsible for these changes, although it has been suggested that a fall in the availability or activity of insulin might be responsible (Wright et al., 1974). Cyclic AMP is believed to play a part in the release of many hormones from their cells of origin (Robison et al., 1971).

Nine pigs were subjected to an intravenous glucose tolerance test (0·5 g/kg) during haemorrhagic shock (blood pressure 50 mm Hg). Portal and systemic blood was sampled, and plasma glucose, insulin and cyclic AMP estimated.

Hyperglycaemia persisted until 2 hours after glucose loading, with systemic glucose levels significantly greater than portal glucose levels ($P<0·005$). A significant increase in plasma insulin occurred, with portal levels being greater than systemic levels. Similarly, an increase in plasma cyclic AMP levels occurred, with portal levels higher than systemic levels ($P<0·0005$). A highly significant correlation was found between plasma insulin and plasma cyclic AMP levels ($P<0·0005$).

It is believed that the raised portal cyclic AMP levels are a reflection of the pancreatic insulin release during haemorrhagic shock, although it is not possible to exclude the release of hormones such as glucagon within the portal circulation or changes in cell membrane permeability as being responsible for these changes in plasma cyclic AMP.

30. Changes in plasma cortisol levels during cardio-pulmonary bypass

K. M. TAYLOR, J. V. JONES, M. S. WALKER, L. G. S. RAO and W. H. BAIN, *Cardiac Surgery Unit and Regional Steroid Laboratory, Royal Infirmary, Glasgow*

Plasma cortisol levels were measured before, during and after operation in 12 patients undergoing cardiac surgery. Six patients requiring closed heart procedures exhibited the typical cortisol response to surgical trauma (Franksson and Gemzell, 1954). The other 6 patients underwent open heart procedures using conventional normothermic cardiopulmonary bypass. In the latter group a highly significant reduction in plasma cortisol ($P<0·001$) occurred during extracorporeal circulation (ECC) which cannot be accounted for by the expected dilutional effect of the fluid prime employed in each case.

Tetracosactrin zinc phosphate (Synacthen 0·25 mg i.m.) was administered during bypass in a further 4 patients. In each case there occurred a rise in the plasma cortisol of >200 nmol/l (i.e. a positive response), indicating that in these patients adrenocortical secretion during bypass had been submaximal. This finding contrasts with the previous observations in general surgical patients in whom administration of ACTH during operation produced no further increase in plasma cortisol, suggesting an already maximal response to surgical stress (Hume et al., 1962).

Measurement of the free (non-protein bound) cortisol content in 6 bypass patients indicates that despite the marked fall in total plasma cortisol there is an actual increase in the free cortisol content during the period of bypass.

31. Direct effect of ethanol on the isolated canine pancreas

J. M. FITZPATRICK, O. FITZGERALD, P. FITZGERALD and K. F. MCGEENEY, *Department of Surgery, University College, Dublin*

Some effects of ethanol on pancreatic function have been found to be mediated through the stomach in whole animals. The response of the secretin-stimulated isolated perfused pancreas to ethanol has been investigated in this study.

Experiments were carried out on the totally isolated perfused pancreas of 8 dogs. The glands were stimulated by a constant infusion of secretin (Boots). In 5 dogs 4 u./hr were infused; in 1 dog each 6, 2 and 1 u./hr were infused. The output of the gland was collected in 10-minute specimens for 3 hours. After the first hour three different concentrations of ethanol were infused for half an hour each.

In 4 dogs ethanol dosages of 50 mg, 100 mg and 1 g/hr were used. In another 4 the dosages were 1, 3 and 10 g/hr. Measurements of volume, amylase, lipase and trypsin output were performed.

At low flow rates (1 μl/min) induced by 1 u. secretin/hr ethanol did not cause secretion. At higher flow rates (above 20 μl/min) induced by 4 or 6 u. secretin/hr ethanol stimulated both volume and enzyme output, and also increased enzyme concentration. These studies indicate that ethanol, even in moderate amounts, can stimulate pancreatic secretion in the ecretin-stimulated gland. This effect, without the mediation of other organs, may be a direct one.

32. Femoropopliteal vein bypass: a new approach to assessing 'run-off'

D. CHARLESWORTH, F. D. CAVE, ANNE WALKER and G. P. NAYLOR, *Departments of Surgery and Medical Physics, University Hospital of South Manchester*

One of the factors which influence the outcome of a femoropopliteal bypass is the outflow or 'run-off' from the lower end of the graft. There are several methods of estimating this but none is reliable. We have measured 'run-off' by calculating mpedance to pulsatile flow.

Simultaneous measurements of pressure and flow were made in the common femoral and popliteal arteries before and after operation in 12 patients. The modulus of impedance in mm Hg/ml min^{-1} over a range of 2–6 Hz was calculated by Fourier analysis of the pressure and flow waves. Preoperatively the mean values for impedance of the superficial femoral and popliteal arteries were 0·43–0·84 and 0·8–1·05 mm Hg/ml min^{-1} respectively. In 9 of the 12 patients the popliteal impedance fell to less than 0·4 mm Hg/ml min^{-1} after reconstruction. There was a significant difference between the pre- and postoperative values at each frequency ($P<0{\cdot}004$). All 9 of these grafts remained patent. In 3 patients popliteal impedance remained high and each graft occluded postoperatively.

Similar results were obtained from measurements of common femoral impedance.

We conclude that input impedance gives a good indication of the capacity of the arterial tree to accept an increased flow and may lead to a useful measure of 'run-off'.

33. The haemostatic effect of ethamsylate (Dicynene) in general surgery

R. S. ARNOT, A. RASHID, MARY EVANS and A. V. POLLOCK, *Scarborough Hospital, Yorkshire*

Ethamsylate has been shown in pigs to be an effective systemic haemostatic agent (Deacock and Birley, 1969), reducing the amount of small vessel haemorrhage produced by a dermatome.

To evaluate this drug in a general surgical practice, blood loss during incisions for 285 major intra-abdominal operations was measured by swab weighing. Approximately half the patients were randomly allocated to receive ethamsylate 750 mg intramuscularly before operation, the remainder being controls.

It soon became apparent that blood loss during incision is dependent primarily on surgical technique and the level of blood pressure. In 49 abdominal incisions (made by a consultant) during which the systolic pressure remained at a level more than 40 mm Hg below the patient's normal pressure ethamsylate reduced bleeding to less than half the control mean ($t=2{\cdot}397$, $P<0{\cdot}05$). However, in 86 patients in whom the incisional pressure was near the preoperative level (and larger vessel bleeding therefore more important) those given ethamsylate did not lose significantly less blood than the controls. In the same trial, patients receiving low dose subcutaneous heparin were shown to lose no more blood during incisions than the controls.

The claim that ethamsylate reduces small vessel bleeding appears to be substantiated.

34. Serum, tissue and wound levels of two cephalosporins

B. W. ELLIS, R. C. SPENCER, R. DE L. STANBRIDGE and J. M. SIKORSKI (H. A. F. DUDLEY), *Surgical Unit and Department of Bacteriology, St Mary's Hospital Medical School, London*

Prevention of infection in surgical wounds by the use of systemic antibiotics has a firm experimental and clinical basis. Currently each new antibiotic or combination of agents has to be evaluated by clinical trial which is tedious and may disadvantage a number of the control patients. If an inference about wound concentrations could be made from other data, doses and times of administration might be chosen *a priori* to maximize the effectiveness of any new agent.

We have studied the skin abrasion technique of Raeburn (1971) as a marker for wound concentration of the cephalosporins, cephaloridine and cefazolin. Adult male patients undergoing elective surgery were given 1 g of either cephaloridine or cefazolin with their premedication and 6 and 12 hours thereafter. Blood, exudate and wound drainage concentrations of the antibiotics were determined at intervals during the first 24 postoperative hours. Wound concentrations of antibiotic lagged behind those of blood and the abrasion but more closely approached the latter. Cefazolin wound concentrations were significantly higher than those of cephaloridine.

Simultaneous blood and skin abrasion levels promise to be a rapid and effective means of screening antibiotics for their penetration into wounds and should prove helpful in evaluating proposed dosage regimens of other antibiotics.

35. Serum follicle-stimulating hormone estimation in the investigation of azoospermia

F. J. BRAMBLE, A. L. HOUGHTON and H. S. JACOBS (R. E. WILLIAMS), *The General Infirmary, Leeds, Bradford Royal Infirmary and St Mary's Hospital Medical School, London*

The investigation of azoospermia includes testicular biopsy, usually under general anaesthetic. Patients with a histological picture suggesting obstruction may be amenable to treatment, but those with germ cell aplasia or arrest are at present untreatable.

Franchimont et al. (1972) have observed that when gametogenesis is arrested before spermatid differentiation serum follicle-stimulating hormone (FSH) concentration is raised.

In 18 cases of complete azoospermia we have measured serum FSH and obtained bilateral testicular biopsies. In 13 cases we have evaluated the response of serum FSH to gonadotrophin-releasing hormone (GRH).

All the cases with germ cell arrest prior to spermatid differentiation had elevated basal levels of FSH and an exaggerated response to GRH.

We suggest that it is possible to identify those instances in which testicular biopsy is indicated by estimation of basal serum FSH. The response to GRH may be of diagnostic help in cases with basal FSH concentration at the upper limit of normal. High basal levels of FSH indicate germ cell aplasia or arrest and in these cases a general anaesthetic and testicular biopsy is not helpful and may be avoided.

FRANCHIMONT P., MILLET D., VENDRELY E., LETAWE J., LEGROS J. J. and NETTER A. (1972) Relationship between spermatogenesis and serum gonadotropin levels in azoospermia and aligospermia. *J. Clin. Endocrinol.* 34, 1003–1008.

36. The relationship between spleen size, clinical staging and histological features in breast cancer

J. G. ROBERTS, A. M. MANDER, R. W. FORTT, K. G. LEACH, A. S. BLIGH and M. BAUM, *Departments of Surgery, Pathology, Medical Physics and Diagnostic Radiology, Welsh National School of Medicine and University Hospital of Wales, Cardiff*

Computer analysis of splenic scintigraphs obtained following reinjection of heat-damaged autologous ^{99}Tc^{m}-labelled red cells can accurately assess spleen size (Roberts et al., 1974).

This technique has been used in 60 patients with breast cancer and 6 controls. Cancer patients had significantly larger spleens (138±59 g) than controls (85±32 g; $P<0{\cdot}05$). Early breast cancer patients with tumours greater than 5 cm maximum diameter had spleens significantly larger (153 ± 62 g) than those with tumours less than 5 cm (124 ± 55 g; $P < 0·05$).

Analysis of the 26 patients within whom nodal histology was available showed that patients with involved nodes had larger spleens (147 ± 48 g) than those with negative nodes (109 ± 31 g), but this difference did not reach statistical significance ($0·1 > P > 0·05$).

Tumours were graded histologically into well to moderately differentiated, poorly differentiated and anaplastic. The well to moderately differentiated group had significantly larger spleens (140 ± 67 g) than the control group ($P < 0·05$). The spleens of patients with poorly differentiated tumours were also larger than the controls (146 ± 54g; $P < 0·02$), while patients with anaplastic tumours did not have a significant increase in spleen size (100 ± 35 g).

These results suggest that the splenic component of the host reaction to cancer may be related to tumour volume in all but anaplastic cancers and mirror the behaviour of the reticulo-endothelial system as a whole as judged by the clearance of the colloidal particles (Baum, 1975).

37. Operative mortality and postoperative morbidity of highly selective vagotomy

D. JOHNSTON, *University Department of Surgery, The General Infirmary, Leeds*

Three hundred patients with duodenal ulcer have been treated by highly selective vagotomy (HSV) in Leeds in the past 6 years, without operative mortality. After operation they can be managed without a nasogastric tube or intravenous infusions. However, recent reports of necrosis of the lesser curvature after HSV prompted this survey, in which a questionnaire was sent to surgeons known to be using HSV.

Replies were received from 33 centres: in Europe (19), Scandinavia (10), North America (3) and Australia (1); 4557 patients had undergone elective HSV for duodenal ulcer alone, with 12 deaths (0·26 per cent mortality). Seven of the deaths were due to cardiorespiratory problems or to pulmonary embolism. Seven cases of necrosis of the lesser curve or fundus were reported, with 3 deaths. Approximately half of the surgeons were using HSV for 90 per cent or more of their duodenal ulcer patients, while most of the others were engaged in prospective random trials of HSV. Thirty patients (0·7 per cent) developed gastric retention or ileus in the early post-operative period, but only 5 of these (0·1 per cent) required reoperation. Twenty-nine patients (0·7 per cent) developed persisting gastric stasis several months or years after HSV and most of these patients underwent reoperation.

Necrosis of the upper stomach seems to be a rare but specific complication of HSV. Gastric retention appears to be more frequent after HSV than after vagotomy with drainage. The operative mortality of HSV is less than the reported mortality of vagotomy with drainage (0·8 per cent) or of gastric resection (1–2 per cent).

38. The radio-isotope hepatogram in the diagnosis of jaundice

A. WATSON, D. E. BONE, H. J. TESTA and B. TORRANCE, *Departments of Gastroenterology and Medical Physics, Manchester Royal Infirmary*

The distinction between 'medical' and 'surgical' jaundice is often difficult, owing to the lack of specificity of biochemical liver function tests and difficulty in assessing hepatocellular function and biliary tract patency in the jaundiced patient. A non-invasive isotopic technique which gives reliable information on these parameters and results in a high degree of accuracy in the classification of jaundice is presented.

^{131}I Rose Bengal is administered intravenously, and count rates during hepatic uptake and biliary excretion are recorded over the liver, biliary tract and duodenum using a gamma camera–computer system with an electronic light pencil. Blood clearance is simultaneously measured, and from these data the $T_{\frac{1}{2}}$ of uptake and excretion quotient are determined.

The results of the first 50 examinations show that by qualitative assessment of the uptake and excretory phases of the 'hepatogram', and determination of the $T_{\frac{1}{2}}$ and excretion quotient, jaundice can be classified with a 94 per cent accuracy, often where liver function tests are equivocal or misleading.

It is concluded that this technique enables an accurate classification of jaundice, and by permitting quantitative assessment of hepatocellular function in the jaundiced patient enables this to be studied both during and after recovery from obstructive jaundice.

39. A controlled clinical trial of three methods of perineal wound management following excision of the rectum

T. T. IRVIN and J. C. GOLIGHER, *University Department of Surgery, The General Infirmary, Leeds*

Traditionally, the perineal wound is left open following excision of the rectum. Recently, various methods of primary suture of the perineal wound have been described, and primary wound healing has resulted in a significant proportion of cases (Haxton, 1970; Broader et al., 1974). However, there have been no objective studies of the relative merits of the different methods of perineal wound closure.

Three methods of perineal wound closure were compared in a randomized prospective study of 106 patients undergoing excision of the rectum. In method 1 the perineal wound was partially closed around a corrugated drain. In methods 2 and 3 the wound was closed by primary suture with suprapubic drainage of the presacral space. The pelvic peritoneum was sutured in methods 1 and 2, but not in method 3.

Primary wound healing occurred in 45·2 per cent of patients treated by method 2, and in 42·9 per cent of cases treated by method 3. Operative contamination of the perineal wound had an adverse effect on wound healing ($\chi^2 = 4·50$, $P < 0·05$). The incidence of persistent wound sinuses at 3 and 6 months after primary closure was less than that encountered after open drainage.

It was concluded that primary closure of the perineal wound is the treatment of choice, except in cases in which operative contamination of the perineal wound has occurred.

40. The effect of some autonomic receptor agonists and antagonists on motor activity of the human ureter

N. LONGRIGG (I. E. GILLESPIE), *Department of Surgery, Manchester Royal Infirmary*

Smooth muscle of the human upper urinary tract has been shown to possess α adrenoceptors, β adrenoceptors and muscarinic receptors (Longrigg, 1974a, b). The present study was designed to test the effect of drugs which may hence theoretically be expected to modify ureteral activity in the clinical situation.

Phasic intra-ureteral pressure changes accompanying peristalsis were recorded in 57 female patients by the use of indwelling non-occlusive open-ended fluid-filled catheters. Drug effects were studied in 23 of these patients after pre-liminary control periods of 30 minutes.

Atropine (7 patients, 10 ureters) was without any observable effect upon basal pressure, frequency, form, amplitude or rhythm of the recorded contractions when studied for post-injection periods of 20 minutes. A similar complete absence of effect was noted after propantheline (6 patients, 10 ureters).

Isoprenaline (5 patients, 7 ureters) effected in all subjects a marked decrease in the amplitude of the contraction waves. This depressant effect was maintained throughout the infusion and for approximately 2–5 minutes following termination of the infusion.

Phentolamine (5 patients, 8 ureters) effected a marked decrease in the frequency of contraction, a slight fall in basal pressure and an increase in duration of the contraction waves. Such changes persisted for a minimum of 6 minutes after which there was a return towards control values.

These results clearly indicate the inhibitory effects of isoprenaline and phentolamine on the motor activity of the human ureter. Their effects upon the abnormally hyperactive ureter remain to be investigated.

41. The Doppler scan and deep vein thrombosis

P. FISH, V. V. KAKKAR and T. K. DAY, *Departments of Medical Physics and Surgery, King's College Hospital Medical School, London*

The ultrasonic technique is a quick and simple way of detecting complete occlusion of the popliteal, femoral or iliac veins. It is less reliable, however, in demonstrating extensive early thrombi which often propagate along the veins without producing any significant obstruction. Furthermore, flow in large collaterals or in a very large superficial vein cannot be distinguished from that in the main deep veins and a false negative result is produced. To overcome these disadvantages a new imaging system has been developed using ultrasound, and is described together with the results of its clinical use.

In this new technique a picture of an internal cross-section of a blood vessel is built up on the cathode-ray tube by moving the transducer probe backwards and forwards across the skin surface, so that the ultrasonic beam sweeps across the vessel of interest. Fifty limbs of 41 surgical patients with clinically suspected deep vein thrombosis were examined by Doppler scanning and by phlebography. Thirty of 32 (94 per cent) partially and/or totally occluding thrombi in the popliteal and femoral veins were detected by Doppler scan. There was 1 false positive result and 2 false negative results, the overall level of agreement for positive and negative results being 47/50 (94 per cent).

The Doppler scan provides a suitable alternative to phlebography for confirming the presence of clinically suspected deep vein thrombosis.

42. Metabolic abnormalities in tumour-bearing animals

K. C. CALMAN and R. A. MCALLISTER, *Departments of Oncology and Surgery, Western Infirmary, Glasgow*

The metabolism of non-involved organs of tumour-bearing animals has received little attention, though the potential importance of this in relation to the pathogenesis of cachexia is great. We have studied intermediary metabolism in animals bearing a transplantable tumour (the TLX5 lymphoma) and measured both co-enzyme A levels and energy metabolites in liver and muscle 7 days after transplantation of tumour.

The co-enzyme A levels in the liver of tumour-bearing animals is reduced by 78 per cent ($P<0.001$) and in muscle by 37 per cent ($P<0.05$) when compared with the content in control livers. Similarly, there is a reduction in the energy content of such livers (ATP, ADP, AMP) of 59 per cent ($P<0.001$) when compared with controls.

These figures suggest that in the presence of a tumour the intermediary metabolism in liver and muscle is grossly abnormal. Because of the central role of these metabolites in fat, carbohydrate and protein metabolism, the reductions demonstrated may account for several of the metabolic effects of tumours. Current research is aimed at defining the mechanism of this depression and its relationship to cachexia.

43. The role of prolactin in hypercalcaemia

K. K. MAHAJAN, C. J. ROBINSON and D. F. HORROBIN (I. D. A. JOHNSTON), *Departments of Surgery and Physiology, University of Newcastle upon Tyne*

Hypercalcaemia and hypercalciuria is a significant clinical problem in patients with advanced breast cancer (Galasko, 1972). Prolactin suppression in patients with bony metastases and possible hypercalcaemia is followed by relief of bone pain (Stoll, 1972).

We postulate that prolactin plays a role in these changes. A study was therefore planned to investigate the effect of infusion of prolactin on calcium metabolism in intact male Wistar rats and in animals after parathyroidectomy and thyroparathyroidectomy.

Ovine prolactin (10 μg/hr) was infused intravenously for 18 hours in the experimental animals; the control group received the vehicle alone. Urine was collected throughout the infusion period and blood was collected by cardiac puncture at the end of the experiment. Urine and plasma calcium estimations were done by flame photometry.

Three groups of animals were studied: (*a*) intact animals (18 pairs), (*b*) parathyroidectomized animals (7 pairs), (*c*) thyroparathyroidectomized animals (13 pairs), receiving appropriate parathyroid and thyroid hormone replacement.

Prolactin caused a significant hypercalcaemia in all three groups and significant hypercalciuria ($P<0.05$) in the intact and thyroparathyroidectomized groups.

Plasma calcium (mg/100 ml)

Intact		PTX		TPTX	
Control	Exp.	Control	Exp.	Control	Exp.
10·22 ±0·39	10·72 ±0·31	4·9 ±0·22	6·06 ±0·66	8·60 ±0·64	9·90 ±0·21
$P<0.025$		$P<0.05$		$P<0.025$	

PTX, Parathyroidectomized. TPTX, Thyroparathyroidectomized animals. Exp., Experimental.

It is concluded that sustained increased levels of prolactin produce hypercalcaemia and hypercalciuria in rats. These findings support the hypothesis that prolactin may be a factor in the hypercalcaemia of malignancies.

STOLL B. A. (1972) Brain catecholamines and breast cancer: a hypothesis. *Lancet* 1, 431.

44. Cholelithiasis—a metabolic consequence of ileostomy

W. S. J. MAIR, G. L. HILL and J. C. GOLIGHER, *University Department of Surgery, The General Infirmary, Leeds*

A clinical and radiological survey of the incidence of cholelithiasis in 106 ileostomy patients was undertaken and the findings compared with the expected incidence calculated from three large scale necropsy series. Twenty-six patients were found to have gallstones (24·5 per cent) compared with an expected number of between 7·6 and 9·5, the difference being statistically highly significant. The male : female incidence ratio was similar to that found in the necropsy series. Eight out of 47 patients under 40 years of age (17·0 per cent) and 18 out of 59 patients over this age (30·6 per cent) had gallstones, the expected incidences being 2·1 and 13·4 per cent respectively.

Patients with an ileal resection of more than 10 cm, whether the primary condition was Crohn's disease or ulcerative colitis, and Crohn's disease patients with a resection of less than 10 cm showed a significantly increased incidence of cholelithiasis; between three and seven times the expected figures. The incidence in ulcerative colitis patients with an ileal resection of less than 10 cm was not significantly increased.

It is suggested that the difference in incidence between Crohn's disease and ulcerative colitis patients with minimal ileal resection may be due to asymptomatic residual or recurrent lesions in the former condition. The importance of preservation of the terminal ileum at proctocolectomy for ulcerative colitis is emphasized.

45. Adjuvant intravesical thiotepa and bladder tumour recurrence

P. J. R. BOYD and K. G. BURNAND (C. JAMIESON), *St Thomas's Hospital, London*

The anatomical sites of mucosal primary and recurrent transitional cell bladder tumours have been studied prospectively in 32 patients. Primary tumours were found on the base and walls in 30 patients and on the vault in only 2 patients. All the patients were treated endoscopically and were followed up for between 2 and 5 years. During this period 31 patients developed recurrent tumour. In 29 patients the vault was at some stage involved by recurrent tumour. In 7 patients recurrences were limited to the vault.

We suggest that the high proportion of vault recurrence results from implantation of tumour cells at the time of cystodiathermy. In an attempt to reduce the incidence of recurrent tumour a further group of 19 comparable patients was prospectively treated with single dose intravesical thiotepa on completion of cystodiathermy.

In this group 11 patients have developed recurrent tumour but in none of these patients was the vault alone involved. Eight patients remained entirely free of tumour.

The significance of these findings suggests that adjuvant intravesical thiotepa reduces tumour recurrence, possibly by the prevention of cellular implantation.

46. Surgery, the contraceptive pill and postoperative deep vein thrombosis

V. V. KAKKAR, A. F. HIGGINS, S. SAGAR and T. K. DAY, *Department of Surgery, King's College Hospital Medical School, London*

A causal relationship between the use of oral contraceptives and deep vein thrombosis (DVT) occurring in previously healthy women has now been established (Royal College of General Practitioners, 1967). It remains to be determined whether (*a*) conditions known to predispose to thromboembolic disease (such as surgical operation) greatly increase this risk and (*b*) any blood test can be used to identify before surgery the patients likely to develop this complication.

Thirty-seven patients undergoing abdominal surgery were investigated and the ^{125}I-fibrinogen test used to determine the incidence of DVT. Frequent blood samples were withdrawn before, during and after surgery to determine the levels in the inhibitor to activated Factor X (Anti-Xa), a protein moiety thought to play a key part in the coagulation process. Six of 22 patients (27 per cent) on the pill developed DVT, but none of the 15 patients not taking the pill did so; this difference is statistically significant ($P < 0{\cdot}05$). All the patients on the pill had low Anti-Xa levels before surgery as compared with those not taking the pill, and levels were further reduced during surgery in those who developed DVT.

These preliminary findings suggest that the use of the contraceptive pill increases the risk of DVT in patients undergoing surgery and that abnormally low Anti-Xa levels before surgery may identify these 'high risk' patients.

ROYAL COLLEGE OF GENERAL PRACTITIONERS (1967) Oral contraception ana thromboembolic disease. *J. R. Coll. Gen. Pract.* **13**, 267–279.

47. Emotional distress in patients attending a breast clinic

E. C. G. LEE and G. P. MAGUIRE (H. A. F. DUDLEY), *Nuffield Department of Surgery and Department of Psychiatry, University of Oxford, Radcliffe Infirmary, Oxford*

Four hundred women referred to the Breast Clinic of the Department of Surgery completed the Spielberger Stait anxiety and Zung depression scales. Before attending the clinic these women were significantly more anxious than were women attending general surgical clinics. Forty-five per cent of the breast clinic group had abnormal scores compared with 18 per cent of a control group. Although there was a significant drop in anxiety after attending the clinic, those being admitted for biopsy and those diagnosed clinically as having cancer improved least. The same group showed a significant lack of improvement in their depression scales before and after attending the clinic.

At the clinic the communication between surgeon and patient was monitored by independent observers. There was a striking discrepancy between the level of distress detected by the mood scales and that indicated verbally by the women to the surgeon. Sixty-nine per cent of the patients exhibited non-verbal signs of distress which were usually ignored by the surgeon. Subsequent home interviews of the patients and their husbands showed that a significant proportion of these women remained very distressed until the time of operation.

When reassessed 3 months after operation 34 per cent of the cancer patients were still reporting moderate or marked degrees of anxiety or depression compared with 7 per cent in the control group. Although in the patients so far studied there has been an improvement in these parameters at the end of 1 year, there has been an increasing incidence of marital discord, sexual problems and a diminution in leisure and social activities. Similar disturbances have been found in their husbands.

48. The thymic hormone and cellular immunity

G. W. ODLING-SMEE, J. G. CAMBLIN and A. D. ROY, *Department of Surgery, Queen's University, Belfast*

Evidence has accumulated that the thymus produces a humoral agent which has the ability to promote a lymphocytosis in thymectomized animals. This material has been shown to change uncommitted lymphocytes into T cells.

In this experiment a bovine thymus extract was prepared by ammonium sulphate precipitation and gel column separation. This purified extract was used to promote *in vitro* lymphocyte cytotoxicity from patients with osteosarcoma towards their own tumour cells, and of normal lymphocytes against a chemically induced rodent fibrosarcoma. The amount of preincorporated isotope tracer, ^{125}I-iodo-desoxyuridine, released from the tumour cells during the period of the reaction was detected and compared with that when cyclophosphamide, PHA or liver extract was added to the culture medium. An attempt was also made to determine the molecular weight and the amino-acid content of the active agent, thymosin.

The results revealed that there was only minimal unstimulated cytotoxicity against both tumour types. The addition of thymosin to the culture medium produced significantly more cell deaths than when cyclophosphamide, PHA or liver extract was added to the medium. Preliminary *in vivo* studies suggest that injections of thymosin may delay the onset and reduce the incidence of chemically induced tumours.

49. Salbutamol: inhibition of gastric ulceration in the rat

L. P. FIELDING, M. ROUTER and B. P. CURWAIN (H. A. F. DUDLEY), *Surgical Unit and Department of Physiology, St Mary's Hospital Medical School, London*

Induction of acute gastric ulceration in the rat with indomethacin is a widely used technique for the initial study of drugs which may be useful in the treatment of peptic ulceration (Robert et al., 1968). We have studied the effect of the β_2 adrenergic stimulant, salbutamol, on the occurrence of such gastric ulcers.

After 24 hours' starvation, rats were divided into four groups. Normal saline or salbutamol was injected subcutaneously at 0, 120 and 240 minutes; normal saline or indomethacin was injected at 15 minutes, according to the schedule shown in the table. The rats were killed at 300 minutes. Each stomach was fixed in a mixture of formaldehyde and alcohol, then opened and photographed. These photographs were enlarged by projection and the length of each ulcer was measured. The total length of ulceration is recorded in the table.

	Group			
	I ($n = 10$)	II ($n = 16$)	III ($n = 10$)	IV ($n = 12$)
Injection at 0, 120 and 240 min	Saline 0·5 ml	Saline 0·5 ml	Salbu. 2 mg/ 100 g	Salbu. 0·02 mg/ 100 g
Injection at 15 min	Saline	Indo. 2·5 mg/ 100 g	Indo. 2·5 mg/ 100 g	Indo. 2·5 mg/ 100 g
Mean length of ulceration ± s.e.m. (mm)	0	21·2 ± 5·2	0	5·7 ± 1·9

Salbu. = salbutamol. Indo. = indomethacin.
Comparisons (Mann–Whitney *U*-test): Groups II and III, $P<0{\cdot}002$; Groups II and IV, $P<0{\cdot}02$.

Salbutamol protected the animals from developing peptic ulceration; the higher dose afforded complete protection while the lower dose greatly reduced the degree of ulceration.

It is concluded that salbutamol should be evaluated for its role in the treatment of peptic ulcer in man.

50. Low dose heparin prophylaxis against pulmonary embolism

S. SAGAR and M. M. KOSHI (V. V. KAKKAR), *North Staffordshire Hospital Centre, Stoke-on-Trent*

The established fact that low dose heparinization is an effective prophylaxis against postoperative deep vein thrombosis (Sharnoff and DeBlasio, 1970; Kakkar et al., 1972) in 'high risk' patients leads inevitably to the question—Is this prophylaxis also effective in reducing postoperative mortality due to fatal pulmonary embolism? A prospective randomized controlled trial was carried out at the North Staffordshire Hospital Centre, Stoke-on-Trent, during the 12-month period April 1973 to March 1974 to study the efficacy of low dose heparin prophylaxis against fatal pulmonary embolism. Five hundred patients over the age of 50 years undergoing elective major surgery were included, of whom 252 received perioperative heparin. Two thoracic, one urological and five general surgeons took part in the trial. In 60 of the 66 patients who died post-mortems were performed by independent consultant pathologists who did not know whether or not the patient had received heparin. None of the heparinized patients died of fatal pulmonary embolism but 8 of the 240 control patients died from this condition. These findings are statistically significant ($P<0{\cdot}05$ with Yates's correction).

There was no evidence from coagulation studies, wound drainage charts or blood transfusion requirements that low dose heparin increased the risk of operative or postoperative bleeding or of wound haematoma formation. Our conclusions are that low dose heparin prophylaxis should be used in all 'high risk' patients undergoing major thoracic, abdominal or urological surgery.

51. Non-invasive investigation for carotid arterial disease by comparison of the characteristics of the supra-orbital and upper limb arterial pulses

M. DE BURGH (H. H. G. EASTCOTT), *Flow Laboratory, St Mary's Hospital, London*

The presence of obstruction or non-laminar flow at the carotid bifurcation might be expected to alter the arrival and form of the supra-orbital pulse wave. We have used mercury strain gauges on the supra-orbital notch and forearm linked to a chart recorder running at 100 mm/sec to ascertain if the diseased bifurcation is detectable. Two variables were studied: the difference between time of arrival of the wave (LAG) and the difference in wave rise time (DRT). Vessels were classified arteriographically as normal (56), partly obstructed (less than 70 per cent of diameter, 46) and obstructed (more than 70 per cent, 18). Both LAG and DRT discriminated between all groups with *P* values of less than 0·001 (Student's *t*-test). Normal distribution of the data permitted application of tolerance limits with confidence probabilities; these indicate that, accepting a 5 per cent error of the second kind, normal is distinguishable from obstruction by LAG with a 5 per cent probability of a false positive and a 25 per cent chance of a false negative or vice versa. Similarly DRT separates partly obstructed from normal with a 10 per cent probability of both a false negative and a false positive diagnosis.

The test is simple and easy to apply, the tolerance limits are acceptable for initial screening and DRT has the particular advantage of detecting minimal disease which may be a source of athero-emboli (Atik et al., 1973).

52. Radiation dosage in mammography

D. L. ASBURY and P. G. BARKER (R. A. SELLWOOD), *University Hospital of South Manchester*

The feasibility of providing a screening programme for the early detection of carcinoma of the breast depends partly on the dose of radiation applied at mammography. In this study mammography was carried out in 150 women by means of a Watson Mammostand with molybdenum targets of 0·8 and 2·0 mm size. Radiation dosage was recorded by the lithium fluoride thermo-luminescent method and the following principles were defined:

1. The dose of radiation was greatest in the upper inner quadrant.
2. It was greater for the mediolateral view than the craniocaudad.
3. There was no detectable dose to the gonads.
4. The dose was significantly greater in young women.
5. Compression of the breast reduced the dose by up to 50 per cent.

Different film and film–screen combinations were assessed. The latter were vacuum-packed. The following total doses to the upper-inner quadrant were recorded:

Kodak industrial quality film	4·9 R
Agfa-Gevaert-Medichrome film with Kodak screen	1·1 R
Agfa-Gevaert Medichrome film with Ilford screen	0·5 R
3M Trimax XD film and Trimax Alpha-4 screen	0·18 R

A 97 per cent reduction in the dose of radiation was achieved from a mean of 4·9–0·18 R.

53. The effect of highly selective vagotomy and truncal vagotomy with pyloroplasty on gastric emptying of solid food in man

H. J. SHEINER, H. L. DUTHIE, D. C. BARBER and P. J. HOWLETT, *Departments of Surgery and Medical Physics, Sheffield Royal Infirmary*

This study was undertaken to assess the theoretical advantage of highly selective vagotomy (HSV) over truncal vagotomy with pyloroplasty (TV) in maintaining better control of gastric emptying (Johnston and Wilkinson, 1970). Twenty-eight male patients with uncomplicated duodenal ulceration requiring surgery were randomly selected to have either a HSV (14) or TV (14). Gastric emptying studies were carried out using a gamma camera and ^{113m}In–DTPA-labelled solid meal.

One week postoperatively the half emptying time ($T_{\frac{1}{2}}$) was considerably longer for HSV ($P<0{\cdot}005$) and TV ($P<0{\cdot}005$)

groups compared with that before operation (48·5 minutes) or normal subjects (53·0 minutes). By 1 month gastric emptying was still delayed in the TV patients ($P<0{\cdot}01$) compared with normal but not in the HSV group. At 6 months postoperatively the emptying times of both groups had decreased (HSV, 53·2 minutes; TV, 72·0 minutes), but there was no significant difference between operations.

The pattern of emptying was determined by the technique of principal component factor analysis. At 1 month both HSV ($P<0{\cdot}1$) and TV ($P<0{\cdot}05$) differed from preoperative patterns without a significant difference between the two groups. By 6 months the pattern of both HSV and TV groups was similar to preoperative and control patterns.

JOHNSTON D. and WILKINSON A. R. (1970) Highly selective vagotomy without a drainage procedure in the treatment of duodenal ulcer. *Br. J. Surg.* 57, 289–296.

54. Insulin response to carbohydrate infusions in surgical patients

B. J. ROWLANDS, A. E. B. GIDDINGS and R. G. CLARK, *University Surgical Unit, Northern General Hospital, Sheffield*

Intravenous fructose and sorbitol may be used as an alternative to glucose in supplying calories. They have a theoretical advantage of being more rapidly metabolized and are said to be utilized independently of insulin (Miller et al., 1952; Lee et al., 1972). This could be beneficial in postoperative management. This study defines the insulin and glucose responses to carbohydrate infusion in surgical patients.

Three groups of male surgical patients received a 2-hour infusion of 30 per cent carbohydrate solution (glucose, fructose, sorbitol) pre- and postoperatively in a therapeutic dosage. Preoperatively there was no significant rise in plasma glucose or plasma immunoreactive insulin (IRI) during fructose or sorbitol infusion. Basal plasma glucose and plasma IRI levels were significantly raised in all groups postoperatively ($P<0{\cdot}01$ and $P<0{\cdot}001$ respectively). Fructose and sorbitol groups showed a significant rise in plasma glucose ($P<0{\cdot}005$) and a highly significant rise in plasma IRI ($P<0{\cdot}001$) at the end of the postoperative infusion. Fructose and sorbitol tolerance were unchanged.

Following operation both fructose and sorbitol produce an insulin response that was not previously evident. This may indicate a postoperative change in the sensitivity of pancreatic islet cells or in insulin metabolism.

55. Steroid and protease inhibition in refractory shock

J. A. R. SMITH, J. N. NORMAN and G. SMITH, *Department of Surgery, University of Aberdeen*

Refractory shock is not common, its nature is obscure and its prognosis poor. Aggressive conventional treatment fails to improve the situation, and pharmacological doses of steroids are popular as therapy. Alternatively, protease inhibitors have been advocated but their use is controversial. Therefore it seemed desirable to compare the use of these agents in refractory shock, using a standard canine shock model.

Refractory shock was induced in four groups by bleeding into a reservoir and maintaining the mean aortic pressure at 40 mm Hg for 2 hours before reinfusion (Wiggers et al., 1948). Methyl prednisolone 30 mg/kg i.v. was given to one group at the time of bleeding, and to another 1 hour later. Aprotinin (Trasylol) 30 000 K.i.u./kg stat. and 10 000 K.i.u./kg hr^{-1} i.v. thereafter was similarly administered to the remaining groups.

When administered before the induction of shock Trasylol maintained cardiac output at a higher level ($P<0{\cdot}005$) and total peripheral resistance at a lower level ($P<0{\cdot}005$) than in the steroid or untreated groups, with improved oxygen availability ($P<0{\cdot}025$) and repayment of oxygen debt. When given after 1 hour of hypotension Trasylol did not affect these parameters.

Methyl prednisolone at the induction of hypotension had a similar but less significant effect on these parameters than Trasylol. Used after 1 hour of shock it increased cardiac output ($P<0{\cdot}01$), oxygen availability, repayment of debt and reduced both total peripheral resistance and the increase in arterial lactate.

Trasylol is therefore effective in ameliorating the situation if given before the development of shock, while methyl prednisolone effectively improves the developed shock state. It is suggested that this may be related to the different modes of action of these drugs.

WIGGERS H. C., INGRAHAM R. C., ROEMHILD F. and GOLDBERG H. (1948) Vasoconstriction and development of irreversible hemorrhagic shock. *Am. J. Physiol.* 153, 511–522.

56. Selective denervation in the treatment of paralytic scoliosis based on electromyographic studies of erector spinae and quadratus lumborum

D. H. R. JENKINS, *University Hospital of Wales, Cardiff*

Electromyographic (EMG) studies were performed on the paraspinal and lateral trunk flexor muscles in 40 children with paralytic scoliosis. Clinical assessment of the activity of erector spinae showed a low correlation with EMG findings. A high degree of correlation was found in quadratus lumborum.

Three distinct patterns of electrical activity and muscle function were observed in patients in whom clinical examination suggested only one main paralytic pattern.

The procedure of selective denervation of particular muscle groups was developed on the basis of the electromyographic findings and one such case was described and illustrated.

Br. J. Surg. Vol. 62 (1975) 165–168

Reviews and notices of books

The Ductus Arteriosus

Donald E. Cassels, MD, Chicago. 235×160 mm. Pp. 345+x, with 143 illustrations. 1973. Springfield, Ill.: Charles C. Thomas. $17.75.

THIS monograph on the ductus arteriosus is written by the Professor of Paediatric Cardiology at the University of Chicago and is clearly addressed to other paediatricians, for there is scant reference to persistent patency in the adult. In the 'developed' world concentration on the problems during childhood may well be justified as most clinicians follow the author's recommendation that a persistent duct should be closed surgically before the child goes to school unless there is some specific contra-indication, and consequently there are very few adolescents or adults with persistent patency in the population.

It is a pity that there is no chapter on the problems associated with surgical treatment, but the surgeon will glean valuable scraps of helpful information by reading this book.

Throughout the book there is extensive reference to the literature, but the reviewer wishes that the author had more frequently summarized this and expressed his own opinion.

Many of the illustrations are excellent, especially the line drawings, but some of the photographs would be more quickly understood if the structures were labelled with initials. The reader would have been saved some justifiable irritation if more care had been taken to present the illustrations correctly. For example, Fig. 118 is upside down, Fig. 121 is apparently absent but in fact appears as Plate 1 at the beginning of the book, Figs. 135, 134 and 133 are presented in that order whereas the text refers to them in numerical order and, most confusing of all, Fig. 137 should appear as Fig. 138 and vice versa in order that the captions may apply to the correct figures.

Following an introduction and a statement on the problem of persistent patency there are interesting chapters on the history, embryology and histology of the ductus arteriosus. Subsequently the anatomy is clearly described, although the statement on p. 61 that the ductus may open into an aneurysmal dilatation at the point of junction with either the pulmonary artery or aorta might be amplified by stating that there is always a fusiform dilatation of the aorta at the site of attachment of the duct except in small children.

Following a short chapter on innervation of the duct, the various theories of closure which have been promulgated are described, but Professor Cassels does not express his own views. Chapter 10 is entitled The Patent Ductus Arteriosus, and there are some who would argue that 'Persistent' would be preferable to 'Patent' as a ductus is, by definition, patent. This chapter includes a quotation from Gibson (Edinburgh) on the criteria required for the diagnosis of patency 'which have not been improved upon'. Figure 40 depicting the various conditions which may simulate a persistent duct and which have to be considered in the differential diagnosis is most useful (the only omission is an arteriovenous fistula between the internal mammary vessels which the reviewer has experienced on one occasion).

There is a lucid chapter on haemodynamics which includes reference to the forward flow in the aortic arch in diastole as well as in systole, and the suggestion is made that this may rob the coronary arteries of their normal flow, a phenomenon referred to as 'coronary steal'. This chapter is followed by a detailed description of the various forms of coarctation which may be found in association with a ductus. Subsequently pulmonary hypertension in association with persistent patency of the duct is discussed in detail, and the indications for surgical closure of the duct in patients with a raised pulmonary vascular resistance are stated on p. 200, but it would have been helpful to surgeons if the indications had been discussed in greater depth.

There is much of interest in the chapters which follow but space does not permit critical review of the subjects covered except to comment that petechiae in subacute bacterial endocarditis are no longer considered by cardiologists to result from arterial emboli. Hence, their appearance in cases of infection of the duct does not necessarily indicate dissemination of emboli via the aorta as stated in the chapter on pathology.

Undoubtedly all paediatric cardiologists should read this book, which, by present day standards, is reasonably priced.

O. S. TUBBS

Clinical Cardiac Radiology

Keith Jefferson, London, and Simon Rees, London. 286×222 mm. Pp. 314+xi, with 377 illustrations. 1973. London: The Butterworth Group. £15.

THIS excellent work succeeds in its intention as a practical book for radiologists and for physicians and surgeons who use the chest radiograph as part of the clinical examination. The book is divided into two parts. The first part consists of a description of the general radiology of the heart and of other systems in heart disease. The second half considers cardiac lesions in clinical groups. There is in the first half a very good description of bone changes in heart disease based on the St Cyres Lecture given by Jefferson in 1971. The material for the book is based on 1500 cases in whom the anatomy and physiology are known from the National Heart Hospital, London, and the clinical practice at that hospital to some extent influences the bias of the book. The congenital heart lesions are mainly in older children and there is little neonatal cardiology. A computer analysis of the material is given in an appendix, and conclusions drawn from this are less helpful than might be expected. The book is very well written, concise and easy to follow. The quality of the 377 illustrations is first class. There is very good correlation of the plain radiograph with the angiogram, and they are both related to the clinical presentation. Barium swallow examination, now not practised as a routine, is perhaps neglected in the description of many of the congenital heart lesions, where it might, in fact, be helpful. The book is, however, to be recommended highly to both radiologist and clinician, for it contains a wealth of material of value to both.

I. H. KERR

Tumours of the Male Genital System

F. K. Mostofi and Edward B. Price, Washington. 260×200 mm. Pp. 310+xiv, with 295 illustrations. 1973. Washington: Armed Forces Institute of Pathology. $8.

TWENTY-ONE years ago the US Armed Forces Institute of Pathology gave us their first fascicle on tumours of the genito-urinary system. It was profusely illustrated, and its excellent text was based on the huge material gathered at the Walter Reed Hospital and the Institute of Pathology. 'Dixon and Moore' became the standard and hallmark of North American pathology, and was to be found on the workbench of pathologists dealing with genito-urinary specimens the world over. Pathologists will not need any review to make them buy this new edition—but what about surgeons? What is in it for them?

The surgeon likely to operate on the prostate, testicle, urethra or penis is bound to find this work useful and interesting. If he works in Britain the most illuminating chapters will be those on the testis and the prostate, his colleagues in Africa may well find the chapters on the urethra and penis more immediately useful. All will have occasion to refer to the work when confronted with problems in any of these organs.

The account of testicular tumours will concern many of us most deeply, since we simply do not know what is best for the young man who presents with a tumour which is not a seminoma.

Our colleagues in North America vie with each other to produce more and more astonishing statistics in favour of radical retroperitoneal node dissection; radiotherapists in the United Kingdom produce even better figures for one group of teratomas, but not for the others. When we try to compare British statistics with those from North America we are entirely frustrated by the impossibility of translating the 'Dixon and Moore' system into the British Testicular Tumour Panel classification ('Collins and Pugh'). Nor do we find anything more accurate in the Dixon and Moore system, as a means of determining prognosis, than the classification of Collins and Pugh, whose distinction between undifferentiated and intermediate teratomas clearly marks out the sheep from the goats. Alas, Mostofi and Price make the comparison no easier, and the simple surgeon who wants to know when (if ever) he ought to do a node dissection on a given patient is as lost as ever.

As for the prostate, Mostofi and Price give a fascinating account of benign and malignant change in the gland in a section full of experience and wisdom, but it was odd to find them claiming value for histological grading in prostatic cancer, when Mostofi and Byar have just stated that any given prostatic cancer will display the entire spectrum of tumour grades if it is examined carefully by the step-section technique. What is the poor old surgeon to believe, and what ought he to do when confronted by the patient from whom he has just obtained a fragment of tissue with a needle biopsy?

Few of us see many disorders of the urethra, seminal vesicles or penis, but when we do, this is surely one of the most illuminating works of reference we can consult. It is richly illustrated with many fine colour plates, and it is unbelievably cheap by present day standards. Indeed, such a fine book deserves a better binding, and it would still be a bargain if one had those cruel staples taken out and the work rebound in a manner more suited to its quality.

JOHN BLANDY

Blood Compatible Synthetic Polymers

Stephen D. Bruck, Maryland. 235 × 160 mm. Pp. 131 + x, with 68 illustrations. 1973. Springfield Ill.: Charles C. Thomas. $9.75.

In this day of increasing specialization it is a delight to see a book written especially to bridge one of the 'gaps'. The book is divided into three sections: (1) the chemistry of polymers; (2) basic physiology of blood; (3) the problems of blood and polymer interaction. Each part is dealt with clearly and concisely and the whole is extremely readable. For its small size the book is comprehensive and should be particularly suitable for polymer scientists wishing to understand the basic biological problems and for medical practitioners wishing to have an improved knowledge of the many diffculties with synthetic polymers in use in medical practice today. It is this latter group who I think will find it particularly useful for background understanding. However, as this book sits so firmly astride two differing disciplines it may well be largely ignored by the two groups and not reach the audience it deserves. At approximately £4 it is expensive but nevertheless a well worthwhile investment for an individual or department involved in the use of synthetic polymers in surgical practice.

A. J. BELLINGHAM

Immunological Aspects of Transplantation Surgery

Edited Roy Calne. 215 × 155 mm. Pp. 342. Illustrated. 1974. Lancaster: Medical and Technical Publishing Co. Ltd. £7·50.

Surgeons who become involved in clinical organ transplantation require a working knowledge of immunology, transplantation biology and genetics in addition to their traditional surgical skills. These subjects are studied mainly by laboratory-orientated scientists who have little opportunity to become conversant with the clinical problems arising in transplantation surgery. The gulf that has always tended to exist between them and their clinical colleagues has become wider in recent years as laboratory techniques have become more complicated and ideas have developed along lines that are sometimes almost incomprehensible to a clinician without special training in the subject concerned.

This book makes a timely attempt to bridge the gulf. It is not a textbook but a collection of essays dealing with the immunological aspects of transplantation biology that attract the most interest, and upon which most research is concentrated at the present time. Professor Calne has assembled a strong team of authors, all of whom are recognized experts in their own fields. There is some repetition but, as Professor Calne explains in the introduction, this has been allowed deliberately so that the reader can see how different contributors interpret the same concepts. Editorial policy has encouraged the authors to distinguish between what is factual and what is speculation. They also try to indicate the phenomena that do not fit in with currently accepted theories because, as Professor Calne points out, it is the study of these that may well lead to new concepts in transplantation biology.

This is a book that will be of great interest to anyone concerned with organ transplantation. Those new to the subject will find it easy to understand. The more experienced will find it a most useful source of up-to-date information.

BERNARD NOLAN

A Synopsis of Anaesthesia

J. Alfred Lee and R. S. Atkinson, Southend. Seventh edition. 184 × 121 mm. Pp. 1000, with 31 illustrations. 1973. Bristol: John Wright & Sons Ltd. £5.

Extending to 1000 pages this edition can hardly be considered a synopsis but rather a complete survey of anaesthesia, containing as it does so much basic medical science as well as clinical anaesthesia and related disciplines such as intensive care.

It will be valuable as a ready guide to most aspects of the subject and by giving many key references as footnotes it facilitates further study. If one were to criticize, there is too little guidance on the relative merits of the multitude of anaesthetic drugs and techniques described; this perhaps is inevitable in a book which attempts to cover so much ground

More succinct are the sections on regional analgesia, a subject to which Dr Lee has contributed so much himself. It is to be hoped that readers of this book will be stimulated to make more use of these frequently neglected techniques.

Undoubtedly the seventh edition will prove to be as popular as its predecessors.

B. A. SELLICK

The Spleen

A. I. S. Macpherson, John Richmond and A. E. Stuart, Edinburgh. 235 × 165 mm. Pp. 280 + ix. Illustrated. 1973. Springfield, Ill.: Charles C. Thomas. $15.75.

This comprehensive monograph on the spleen combines the personal experiences of a surgeon, a physician and a pathologist. They have produced a full and clear account of the organ from all aspects including the anatomical, physiological and pathological. The diagrams, plates and tables are well produced and aid the reader in a general understanding of the subject. Long-accepted facts and theories are given but particular emphasis is laid on areas of controversy or where recent research has produced new concepts. The book covers items of special interest to the surgeon, and at the beginning of each chapter there is a list of its main contents. Both common and rare disorders are discussed, from the pathological, immunological and clinical points of view. We still do not fully understand the position of the spleen in tissue immunology and its relationship with the lymphocytes' transportation of antigen. There is also the question of the role of the small lymphocyte.

Details of and indications for splenectomy and the merits of operation in different types of splenomegaly follow a chapter on investigation by various methods. The pitfalls and complications and possible methods of avoiding these are also included. The likely prognosis following the operation for particular diseases is discussed. This is a book of interest to the specialist surgeon and also to the general surgeon who has occasion to deal with splenectomy for reasons other than trauma. The monograph contains many points which will tend to lower the morbidity and mortality of splenectomy and is an excellent book of reference in the case of splenomegaly of unknown origin.

PHYLLIS GEORGE

Needle Biopsy

Thomas J. Deeley, Cardiff. 220×145 mm. Pp. 170+viii, with 25 illustrations. 1974. London: The Butterworth Group. £3·50.

THIS valuable monograph allows the reader to benefit from the author's great experience with needle biopsy. The first part of the book deals with apparatus, technique, processing of samples and interpretation. A discussion of advantages and limitations of the technique follows, and the risk of dissemination of malignancy is fully treated. It appears that fears that needle biopsy might be harmful are without rational foundation.

The second part of the book describes the application of needle biopsy to lesions in different organs of the body. The author displays an understandable preference for the high speed drill biopsy apparatus that he invented, but where other techniques are preferable or equally suitable they are described too. For each site in which needle biopsy has been undertaken there is useful information on indication, contra-indication, complications and the potential value of results which may be obtained.

The book is particularly well produced with short sections written in lucid English, 25 useful illustrations and about as many tables, an excellent bibliography and a high standard of printing on excellent paper. It will be of especial interest to surgeons and radiotherapists.

J. H. WYLLIE

The Treatment of Chronic Pain

Edited F. Dudley Hart, London. 220×155 mm. Pp. 191+ix. Illustrated. 1974. Lancaster: Medical and Technical Publishing Co. Ltd. £6·50.

THIS is a valuable book on a neglected subject. Dr Hart includes another physician, two surgeons, an anaesthetist and a psychiatrist, and the six authors set out to consider the 'long pain' and how they attempt to control it. Written for general practitioners and senior students, it should surely serve also as a guide to housemen and registrars, who are often perplexed by the number of people with chronic pain whom they find in their constituencies. Teaching on the subject of pain relief has too often been based on the short term experience of the events of acute pain, disregarding the situations of chronic pain. Perhaps no other situation can make a doctor feel more helpless or more tempted to disappear in a cloud of investigations of doubtful value.

Those of us who are unclear how the complex phenomenon of pain is processed will be glad to find a description of the gate theory given as a useful working hypothesis by Huskisson. He considers the measurement of pain and gives a useful summary of trials carried out in various centres with experimental and pathological pain. He provides a comprehensive list of references.

Pain is a process indissolubly bound up with the personality of the sufferer. This is emphasized by each writer and developed in his own way by Szasz, the psychiatrist. He looks at the 'painful person', the person who has adopted the career of being sick and whose pain cannot be influenced by altering the anatomy or chemistry of his body. Such a patient leaves the physician with the dilemma, 'whose pain shall he control?' Provocative as usual, Szasz's contribution adds its own demand to look at the more ordinary person who feels pain in his wholeness.

Hart deals with the rheumatic disorders, which are responsible for more time off work and disability than any other group of diseases. He gives reviews of the different syndromes and the way he dissects his patients in terms of pains to treat. He sums up the indications for the many drugs available but adds 'Every patient, however, is an individual problem child as regards analgesics'. He introduces us to 'typus robustus'; the person who continues at work with active arthritis, has little pain and does not show progressive joint destruction. The importance of activity, distraction and drugs which help less stalwart characters to disregard their pain is emphasized by several of the authors: 'The occupied mind needs less analgesic than the one wide open to all painful stimuli.' Finding that 'Backache' appears as a title in only two of his own row of textbooks of rheumatology he gives a helpful guide to a constructive look at this most common of complaints.

Westbury discusses the treatment of the painful persistent malignant process. He emphasizes that palliative surgery, indicated in some situations, is no substitute for the general understanding of the patient and his problems. He underlines 'the sense of isolation engendered by being passed by which can never be counterbalanced by any amount of skilled pharmacology'. He gives a brief summary of the radiotherapy and chemotherapy which may still be appropriate at this stage and refers to some of the many analgesics available. The reader is given a helpful introduction to this subject, which is perhaps the most common problem of chronic pain a student is likely to meet in the wards of a teaching hospital. He may perhaps mislead some prescribers when he rightly emphasizes that no patient should be kept waiting for a drug until the chosen routine time, and suggests that analgesics should, at this stage, be used readily to prevent pain from occurring at all. The patient will probably do best if his dose is increased, or has the correct adjuvant added, until pain relief covers the routine time and he does not have to ask at all. A busy nurse will find it easier to give him his drugs with her usual round and it is still too often true, as a medical student said recently: 'In our hospital the patients have to earn their morphia.'

White, who considers the non-malignant neuralgias, has followed over 1000 patients, some for many years, and has found a satisfactory outcome in 74 per cent of his patients. He has reviewed the work of many other clinics and refers us to a larger textbook for the details of the surgical procedures that he outlines. His contribution will help to give the general practitioner sufficient knowledge to make informed referrals for such help for their patients. As he points out, however, 'Nature has an extraordinary ability to find new pathways for conducting pain', and he believes that if the effectiveness of stimulating the pain-inhibitor fibres can be improved, the goal of making the surgeon's efforts more consistent with safer methods may come within our reach.

Feldman refers to the use of various chemicals in nerve-blocking procedures. He feels that the patient can best be seen as a complete person in relation to his environment in a pain clinic where various specialties are involved. He describes the methods used where blocking is indicated and considers its place, advantages and drawbacks and in which direction he thinks more refined methods may be developed.

Specialists in the fields covered in these pages will want to turn to the extensive literature referred to; general practitioners, those taking their final exams and many more besides should read this book. It will help them to develop their own practice in the relief of the pain that brings so many of their patients to them. The comment made by a district nurse about some of her patients, 'They don't know how much pain they are supposed to have', should unfortunately be directed sometimes at the doctors who are looking after them.

CICELY SAUNDERS

Central Rhythmic and Regulation: Circulation, Respiration, Extrapyramidal Motor System

Edited W. Umbach and H. P. Koepchen. 265×180 mm. Pp. 418, with 309 illustrations. 1974. Stuttgart: Hippokrates Verlag. No price given.

THIS book contains the proceedings of an international symposium (with 97 contributors) held in Berlin in 1973 under the auspices of the German Neurovegetative Society to discuss rhythmical control phenomena in the central nervous system. Most of the contributions will be of interest only to experienced experimental physiologists, particularly those involved with the respiratory and cardiovascular systems, but a few might usefully attract the attention of neurosurgeons. Unfortunately, however, much of the book is extremely difficult to read (and parts are quite unreadable) because most of the contributions by non-English speakers have been rendered into obscure and inaccurate pseudo-English, including the title of the work itself, which is mistranslated from German and makes no sense in English. As a good deal of the material is of considerable interest to experimentalists, it is a pity that the contributions (some of them from workers of considerable distinction) are not presented in the native language of the speaker. For these reasons, the book cannot be recommended.

BARRY WYKE

Reviews and notices of books

Stroke. Diagnosis and Management. Current Procedures and Equipment

Edited William S. Fields, MD, and John Moossy, MD. 235 × 160 mm. Pp. 298 + xii. Illustrated. 1973. St Louis, Mo.: Warren H. Green Inc. $15.50.

This small book, which is technically an excellent production, contains the deliberations of a symposium on 'Strokes' held under the auspices of the University of Texas Medical School and the Houston Neurological Society.

The contributors and commentators, who include some thirty-four eminent physicians, neurologists, neurosurgeons, neuroradiologists and neuropathologists, were gathered from many well-known centres in the USA.

Most of the presentations are largely of medical neurological interest including sections on blood flow, laboratory diagnosis and coagulation studies and the use and misuse of anticoagulants. There are also chapters devoted to the problems of management of patients with strokes in the community, in family practice and under intensive care in hospital. In addition there are two chapters concerning the use of angiography in diagnosis.

Two chapters only are primarily of surgical interest: one on occlusive disease of the great vessels of the neck and a second providing a general review of the management of intracranial vascular lesions. Neither, well presented though they are, will carry any new message to those specializing in these fields.

Similarly, the chapters on pathology reveal nothing very new to those engaged in the diagnosis and management of cerebrovascular disease. In short, this book, whilst bringing together the views of a number of experts in this field in a very general way, adds nothing to our knowledge of a very common problem.

B. J. HARRIES

Larrey: Surgeon to Napoleon's Imperial Guard

Robert G. Richardson. 222 × 145 mm. Pp. 266 + x. 1974. London: John Murray Publishers Ltd. £4·50.

A good story can be told many times, and the progress of the battles that carried Napoleon all through Europe, Russia and the Near East during those bloody years of the young nineteenth century loses nothing when the account is as seen through the eyes of the Emperor's surgeon and close and trusted friend. Dr Robert G. Richardson writes well, with economy, style and a scrupulous regard for his sources, which include new material from the collection of the Wellcome Institute. All through this excellent book, which is packed with information of compulsive interest, he takes us lightly from one incident to another, all the while filling in a warm and lively picture of the admirable Larrey, from his early revolutionary days on the barricades to the birth of modern warfare in its new *ad hoc* style, free from the formalities of the past, above all with its conservation of the wounded by rapid evacuation and good field surgery in place of disposal by musket-shot—friend and foe alike. Larrey had the indefinable touch of surgical greatness. He was trusted by all, from a wounded monkey to an impatient general, with compassion that was equal for each and successful with both. He could rise to incredible feats such as the personal conduct of 200 amputations in the first 24 hours of the Battle of Borodino. Earlier, in Palestine, we have the lighter moment when Napoleon kept dinner waiting an hour while Larrey finished at the hospital. Napoleon's regard for his surgeon was matched by Larrey's affection for his Emperor. Such was Larrey's depression during the exile in Elba that he was planning to give up everything and join his master when the news reached him of Napoleon's return.

These are a few of the vast number of items from which one could choose in making this review. Their number will only be exceeded by the many more who will read about them for themselves in this most commendable book.

H. H. G. EASTCOTT

Cancer Handbook of Epidemiology and Prognosis

J. A. H. Waterhouse, Birmingham. 250 × 195 mm. Pp. 195 + ix. Illustrated. 1974. Edinburgh: Churchill Livingstone. £6.

Dr Waterhouse has made a considerable contribution to cancer statistics and has an international reputation in the field. This volume is another example of his prodigious industry.

The book provides detailed information on the incidence of and survival from malignant disease in the United Kingdom, the source of the data being the Birmingham Regional Cancer Registry. This registry provides reliable figures on a population of 5 million persons in central England and generally may be taken as representative of the country as a whole. With an efficiency of registration which has exceeded 95 per cent for the past decade, we can be confident of the completeness of the data.

As indicated by Sir Richard Doll in his foreword to the book, accurate continuous cancer registration is of value for a variety of reasons. The accumulating data enable early recognition of changes in the incidence of disease and in results of treatment; changes which may reflect the advent of new cancer risks or the effect of new methods of detection and treatment.

In this volume the material is presented clearly and succinctly in the form of neat labelled line drawings, graphs and tables. The text is correctly kept to a minimum. An occasional exotic touch is added, such as the attractive colour graph illustrating the varying ages of onset of tumours of childhood. The information is classified according to the site of primary disease and provides details of sex and age distribution. The survival data are presented as 5- and 10-year rates, both in crude terms and adjusted by a life table method to allow for mortality from other causes. An interesting inclusion is the separate survival rates for patients given radical treatment.

This is an extremely valuable book, elegantly produced, easy to handle and reasonably priced. It will undoubtedly become a well-thumbed reference book, particularly for those working in the field of clinical oncology.

IAN BURN

The Structure and Biochemistry of Cartilage

A. Serafini-Fracassini, Padua, and J. W. Smith, St Andrews. 240 × 160 mm. Pp. 236 + vii. Illustrated. 1974. Edinburgh: Churchill Livingstone. £8.

Until recently cartilage has been a somewhat neglected tissue in textbooks on the basic medical sciences. Within the past few years, however, several books have been published which give due recognition to the importance of cartilage in its dual roles as the growth medium of the skeleton and the highly specialized lining surface of joints, and to the vast amount of research which is being devoted to this subject at the present time. Few have contributed more to this new knowledge than the two authors of this volume who have successfully bridged the gulf between their respective disciplines of biochemistry and morphology to produce one of the most up-to-date and comprehensive accounts of cartilage biochemistry and structure.

The book is well illustrated with electron micrographs of excellent quality, although the legends are sometimes inadequate for one not entirely familiar with this medium. The clinician may regret that there is no attempt to relate this wealth of information on normal cartilage to the changes occurring in the disordered state, but this is not the authors' purpose. They have set out to 'bring together some of the existing biochemical, morphological and physiology knowledge of cartilage', and this modest objective has certainly been achieved. This book will be essential reading for all researchers on the connective tissues. Rheumatologists and orthopaedic surgeons will find it a useful work of reference, for the informative text is enriched by an extensive bibliography—nearly 400 items for a single chapter! Not a book for the bedside table, but one which should be available in all medical libraries.

JOHN CHALMERS

ACM endoscopes leave nothing to the imagination

Most surgeons today recognise the superiority of endoscopy as a means of confirming diagnoses of colon diseases. It can be quicker and easier than laparotomy, and is also less traumatic for patients and makes fewer demands on hospital facilities.

The premier instrument for colonic investigations is the ACM F9L coloscope. Advanced features include 12X magnification and a sharp, wide angle circular image three times larger than competitive instrument's.

With it a surgeon can clearly view as far as the caecum, take biopsy specimens and perform polypectomies. After surprisingly little practice, coloscopy can be most rewarding. And the ACM coloscope is exceptionally easy to use – a single, one-handed joystick controls the poly-directional tip.

There's a shorter version, too, the F9S which will reach to the transverse colon and beyond. For the experienced coloscopist there's the dual channel F9A, a major operative, as well as diagnostic instrument.

To find out more, please use the coupon. Or write or telephone.

Please tell me more about ACM endoscopes.

"I Bring Peace"-73

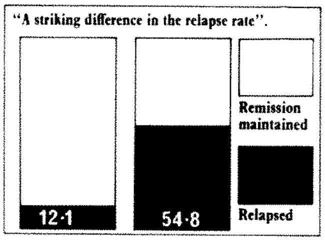
"It is concluded that maintenance treatment of ulcerative colitis with sulphasalazine (salazopyrin) should be continued indefinitely unless contraindicated by side effects".[1]

The results of the above controlled trial carried out at the Nuffield Department of Clinical Medicine, Radcliffe Infirmary, Oxford are all the more welcome as earlier trials of cortisone[2] and prednisone[3] at standard dosages have shown them to be ineffective in reducing the number of recurrences of ulcerative colitis.

"Fortunately, Sulphasalazine tablets, 0.5 grams 4 times a day will prevent relapses in the majority of patients with colitis, and only a few patients cannot tolerate this relatively small dose, which can be continued indefinitely since we do not know when, if ever, it can be safely stopped".[4]

Salazopyrin (sulphasalazine) is available as the plain 0.5g. tablet, 0.5g. EN-tab and as an 0.5g. suppository. Literature and detailed information on Salazopyrin are available on request.

Salazopyrin is a registered trade mark.



"The patients who received dummy tablets had more than four times the relapse rate of those receiving sulphasalazine".[1] (Salazopyrin®).

Both groups of patients had been satisfactorily maintained for 1–5 years on Salazopyrin prior to the study, in which they took Salazopyrin or placebo for 6 months.

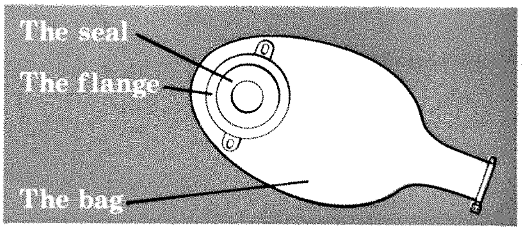
The continuing story of your successful ostomy

Good reasons why REDIFIT is the ostomy appliance for your patient.

Redifit will give added comfort and confidence to the Ostomist because it incorporates the following distinct advantages:



THE SEAL

The seal is of a superior Karaya gum which will not cause any irritation to the most sensitive skin. It will not distort, and will always create a perfect seal with the skin. It is less affected by extremes of temperature and humidity and so will always come to you in perfect condition.

THE FLANGE

This is a new pattern, unique to Redifit. It is not fastened directly to the bag but is held by a collar on which it can rotate. Therefore even after the bag is fixed in position, the angle of the flange can be adjusted to give the most comfortable position for the belt.

THE BAG

Redifit bag has no less than five laminations of plastic, and is guaranteed odour-proof for the normal life of the bag.

With only one layer of film, one cannot be sure of avoiding the embarrassment of escaping odour.

COMPETITIVE COST

Redifit for the special needs of special people

Why run the risk of her cystitis ascending, and the problem of pyelonephritis developing? Rapid, effective therapy with SEPTRIN is indicated at the first opportunity.

SEPTRIN was rated top oral treatment in a British survey of 23,491 urinary pathogen sensitivities.[1] SEPTRIN has been judged superior to ampicillin[2,3] and is now well established as a first-line treatment for urinary infections.

SEPTRIN contains trimethoprim and sulphamethoxazole
Full prescribing information is available on request.

EDITORIAL NOTICES

Original articles or reviews are invited and editorial communications should be addressed to the *Editorial Secretary, British Journal of Surgery, c/o John Wright & Sons Ltd., Bristol BS8 1EX.* Articles are accepted on the understanding that they are contributed to this Journal only, and that articles and their illustrations become the property of the Journal unless the authors state, before publication, that they reserve the right to themselves. Each article should be accompanied by an adequate summary, suitable for publication. Authors are asked to ensure that original illustrations are securely packed and adequately protected.

BUSINESS COMMUNICATIONS should be addressed to *John Wright & Sons Ltd., British Journal of Surgery, Bristol BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery.*

BINDING.—Handsome Cloth Cases may be obtained for binding Vol. 60. Case, £2·00 post free; Case and binding, £7·50 post free. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers, who will also undertake the binding if desired.

ADVERTISEMENTS.—All communications should be addressed to *Hexagon Publishing Co. Ltd., 10 Spencer Street, St Albans, Herts AL3 5EG* (telephone St Albans 60641).

Instructions to Authors

PREPARATION OF MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

ILLUSTRATIONS AND TABLES

Illustrations should be clearly marked on their backs to show number, orientation and author's name. Explanatory legends should be typed on a separate sheet of paper accompanying the manuscript. For halftones, glossy photographs or positive prints (*not* X-ray negatives or slides) should be sent, unmounted wherever possible. When coloured illustrations are submitted as colour prints, they should be accompanied by the original transparencies where possible. As colour illustrations are expensive to reproduce, authors may be asked to make a contribution towards the cost. Drawings should be in a finished state suitable for reproduction. Any lettering should be large enough to withstand a reduction in size; sans serif lettering is recommended.

Tables should be typed on separate sheets of paper accompanying the manuscript. They should have an identifying number and a short descriptive heading. *All illustrations and tables must be referred to in the text.*

REFERENCES

The citation of references should follow the pattern shown in the Reference Citation Recommendations issued by the Medical Section of the Library Association. Copies of these recommendations can be obtained from the Secretary, Medical Section, The Library Association, 7 Ridgmount Street, London WC1E 7AE.

The name of the author and the date of publication are given in the text; the list of works cited is put at the end of the article, arranged in alphabetical order of authors' names. When references to two or more works by the same author are listed, they are arranged in chronological order. Where there are two or more authors (apart from the main author), these may be indicated in the text citation by the words 'et al.', following the name of the principal author; on the rare occasions when this may lead to confusion, the text citation should name as many of the collaborating authors as are necessary to identify the work cited. When several works published by the same author(s) in the same year are cited, they should be distinguished by the letters a, b, c, etc., placed immediately after the date.

In the list of works cited each reference to a *journal article* should give, in the order indicated, the names and initials of all authors, the year of publication (in parentheses), the title of the paper, the name of the journal (abbreviated), the volume number (in heavy type arabic numerals) and the numbers of the first and last pages of the article. Abbreviations for journal titles should be those adopted by *Index Medicus* since January 1971; where no abbreviation is given by *Index Medicus* the journal title should be left in full and the publishers will provide a suitable abbreviation. A reference to a *book* should give, in order, the names and initials of all authors, compilers or editors, the date of publication (in parentheses), the title of the book, the edition number (if other than first), the place of publication, the publisher's name and, where appropriate, the number(s) of the page(s) referred to. A reference to a *contribution to a book* should give, in order, the names and initials of all authors of the contribution, the date of publication (in parentheses) and the title

of the contribution; then, after the word 'In:', there should follow the name(s) and initial(s) of the author(s) etc. of the book, the title of the book, the edition number (if other than first), the place of publication, the publisher's name and the numbers of the first and last pages of the contribution.

Titles of papers and books should be given in the original language, with titles in Cyrillic and Greek alphabets transliterated

Only in papers in which many and frequent references have to be made should the items be numbered; the numbers may then be inserted in the text without interrupting it with a list of names and dates.

INJURY

The British Journal of Accident Surgery

Editor, R. L. BATTEN, FRCS(Eng)

Injury provides a focal point of information for those engaged in the many fields of medicine which accident surgery involves. Contributions from all over the world provide well-organized and comprehensive coverage of every aspect of care of the injured. Original articles take up a large section of INJURY and, as accident surgery is so often concerned with the individual patient, reports of interesting and complex cases are included. To keep the reader informed of the latest progress, INJURY contains details of current research and of new drugs and medical instruments. Reviews of new books appear regularly and, of particular value in a field of medicine which often has a debt to other specializations, INJURY devotes some of its space to abstracts from a wide range of publications on related subjects.

BURNS including Thermal Injury

The Journal of the International Society for Burn Injuries

Editor, J. E. LAING, FRCS

To counter the high mortality and morbidity caused by burn injuries needs the teamwork of a wide range of specialists: treatment of the patient can involve plastic, paediatric and orthopaedic surgeons, biologists, immunologists and bacteriologists, while the rehabilitation of the patient can need the efforts of occupational therapists, physiotherapists, psychiatrists and social workers. This new journal is published to foster the exchange of information amongst all those engaged in preventing and minimizing the effects of burn injuries. BURNS is sponsored by the International Society for Burn Injuries, whose aims are to transcend national boundaries in improving the prevention and care of burns by education, research, practical advice and assistance, and the encouragement of cooperation between all countries and all specialists.

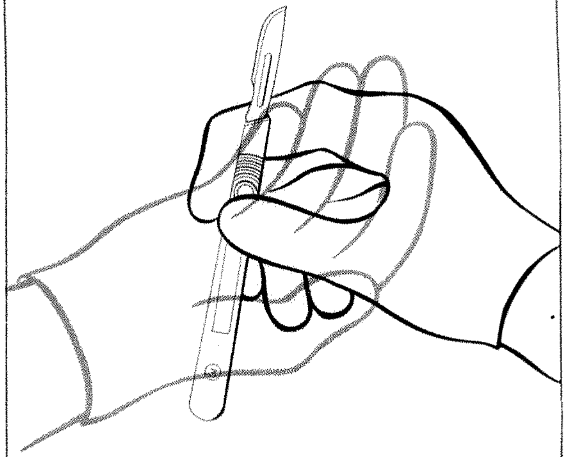
Binding Cases

Binding cases for Volume 61 may be obtained from the Publishers at £2·00 post free. They are supplied in dark red cloth with imitation gold lettering on the spine.

If desired, the publishers will undertake the binding at an inclusive charge of £7·50, post free.

JOHN WRIGHT
42–44 TRIANGLE WEST
BRISTOL BS8 1EX



Another surgeon is about to use one of the world's finest surgical blades.... ...this happens thousands of times every day!

It happens because the blades are by Swann-Morton, the people who meet the highest requirements in surgical knives.

We need say very little about our superiority. The world's surgeons have proved it for us!

Swann-Morton

SWANN-MORTON LIMITED
PENN WORKS, OWLERTON GREEN
SHEFFIELD S6 2BJ. ENGLAND.

SIEMENS

DIATHERMY EQUIPMENT
for modern
ELECTRO-SURGICAL
TECHNIQUES

Available in various designs such as

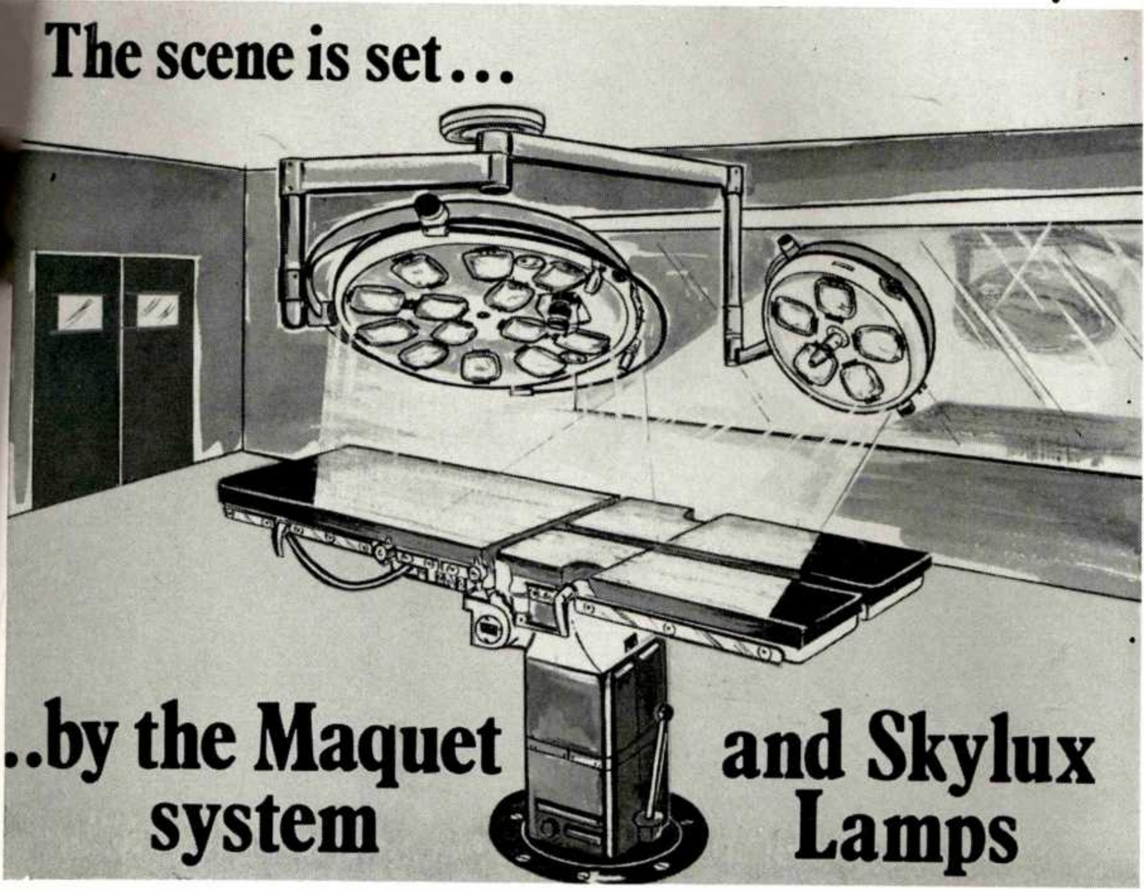
TROLLEY MOUNTED,
CEILING SUSPENSION
or installation in the
OPERATING THEATRE WALL

Full details available on request

Sierex

SIEREX LIMITED Electro-Medical Department,
Heron House, 109 Wembley Hill Road,
Wembley HA9 8BZ. Telephone 01 903 0418

Branches in Birmingham, Bristol, Bury St. Edmunds, Dublin, Edinburgh, Glasgow, Leeds, Liverpool, Manchester, Newcastle and Reading. Agents in Belfast.



Maquet fixed column operating table system

Fixed column–power operated
Extreme stability
Free access for x-ray equipment
Wide variety of table tops
Tops easily interchangeable–increased theatre efficiency
Unique 'Tele' control
Easy clean finish

Skylux Lamps – for all Theatre applications

- High level of light intensity
- Maximum freedom from shadow and glare
- Ideal variation of illumination
- Heat free
- A real white light
- Easy mobility

Catalogues available on request

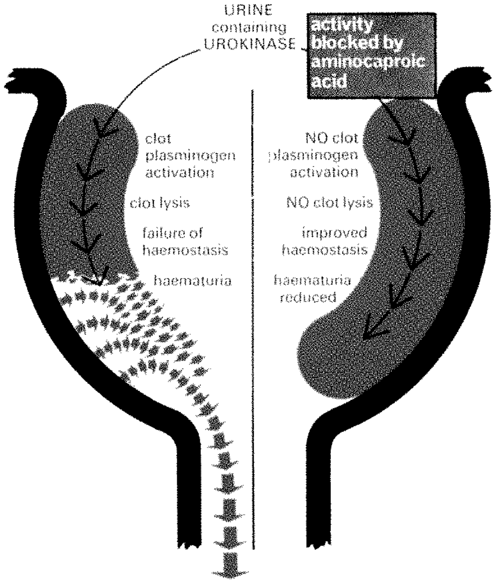
The mechanism of post-prostatectomy bleeding and EPSIKAPRON® control



Epsikapron (aminocaproic acid) is rapidly excreted in the urine in high concentration; there it inhibits urokinase, the fibrinolytic enzyme in urine. With the haemorrhage-sustaining property of urine blocked, the haemostatic coagulum becomes adequate, and blood loss is diminished substantially.

Epsikapron makes your prostatectomy patient's post-operative course smoother by diminishing:

the need for post-operative blood transfusion
clot retention
catheterization
the risk of infection
the period of hospitalization

Presentation

Epsikapron Solution for Injection 0.4 g/ml Box of 6 ampoules of 10 ml, each containing 4.0g aminocaproic acid (0022/5003) Epsikapron Effervescent Powder 50% Box of 30 sachets, each containing 3.0g aminocaproic acid (0022/5004) Epsikapron Syrup 0.3g/ml Bottle of 250ml (0022/5005)

EPSIKAPRON®

Haemorrhagic and necrotizing pancreatitis

GEOFFREY GLAZER*

ACUTE pancreatitis may be a relatively innocuous oedematous reaction or less frequently a severe haemorrhagic and necrotic destruction of the gland. Current views suggest that the latter is an extension of the oedematous reaction rather than a separate entity.

Mortality

A review of published series throughout the world reveals a wide range of mortality which is probably the result of geographical differences (and hence differences of associated aetiological factors), problems in diagnostic classification and variations in treatment. Different series may not be strictly comparable or may be weighted by high or low risk cases: on the one hand, elderly patients or those with postoperative pancreatitis, and on the other hand, patients having their second or third attack. Nevertheless, some broad conclusions can be drawn. The overall mortality of pancreatitis throughout the world varies between 10 and 23 per cent (Zimberg, 1968), with similarly high figures in the United Kingdom (Pollock, 1959; Trapnell, 1972). Haemorrhagic pancreatitis occurs in 10–25 per cent of all cases; the mortality in these patients is much higher, with death rates between 40 and 70 per cent (Barraclough and Coupland, 1972).

Intraduodenal digestion

The exocrine pancreas secretes a large volume of juice which contains water, electrolytes and several digestive enzymes. The proteolytic enzymes exist in this juice as inactive pro-enzymes which become activated in the duodenum by the hormone enterokinase. The key reaction is the conversion of trypsinogen to trypsin, as this then activates the other proteolytic pro-enzymes. Some other enzymes (i.e. prophospholipase A) are activated in the duodenum by bile and calcium ions, while yet others are secreted in their active form (i.e. amylase). Thus, there begins within the duodenum a considerable digestive ferment which is delicately controlled by a complex neurohumoral mechanism. Hermon-Taylor (1972) has recently reviewed this topic more fully for surgical readers.

Development of pancreatitis

There are two stages in the development of acute pancreatitis that must be differentiated; first, the initiation of the condition during which the pancreatic defence mechanisms are overcome and acinar cell damage results, and secondly the pathogenesis of pancreatic necrosis once the initial insult to the gland has occurred. An understanding of the various steps in the progression from oedematous pancreatitis to pancreatic necrosis would lead to a more rational therapeutic approach, but in our present state of knowledge many of these steps are hypothetical.

Pancreatic defence mechanisms

The pancreas possesses several defence mechanisms which prevent autodigestion but once these are overcome pancreatic 'damage' at acinar cell level occurs and pancreatitis ensues. The enzyme-secreting acinar cell protects itself from destruction by storing its enzymes in capsules away from the main cellular components, and by activation of the pro-enzymes in the duodenum. The pancreas also produces a specific pancreatic trypsin inhibitor (PTI), but the importance of this polypeptide in preventing the intrapancreatic activation of trypsinogen is not clear. A fall in the level of PTI secreted on the first postoperative day has been demonstrated in a small group of patients (Morgan et al., 1968), and this finding may be of aetiological significance in postoperative pancreatitis. The pancreatic ductal cells may provide another defence mechanism, but this can be breached under certain circumstances. Perfusion of bile through the duct under physiological pressures will cause no injury, but injection at higher pressures will cause a rupture of the finer ducts. Bile infected with *Escherichia coli* causes a mucolytic and cytotoxic effect on the ductal cells in the cat (Konok and Thompson, 1969), but the relevance of this to the human situation is not known. Retrograde injections into the duct are now performed in man via a fibreduodenoscope in order to obtain pancreatograms. This procedure was associated with abdominal discomfort in a few patients, but almost 50 per cent of these patients had a rise in serum amylase of up to three times the normal value (Cotton et al., 1972). The integrity of the pancreatic duct sphincter is of importance in the prevention of reflux, as is the positive pressure gradient from pancreatic duct to duodenum.

Associated clinical conditions

Biliary tract disease, alcoholism and a miscellaneous group which comprises such diverse conditions as hyperparathyroidism, trauma, infections, postoperative cases, hereditary defects, hyperlipidaemia, drugs and pregnancy are all associated with pancreatitis. In a substantial number of cases of acute pancreatitis there is no obvious associated clinical condition, and this idiopathic group accounts for 40 per cent of the cases reported by Trapnell (1966).

Initiating mechanisms: The manner in which the above conditions initiate pancreatitis is varied and it is proposed to discuss only the main groups of biliary tract disease and alcoholism. For information on the miscellaneous group the reader is referred to recent reviews (Creutzfeldt and Schmidt, 1970; Banks, 1971; Geokas, 1972).

Biliary tract disease: The explanation of the association between biliary tract disease and pancreatitis has been largely based on the reflux theory of altered bile into the pancreatic duct. Little is known of the factors that control or prevent such reflux in man but more is known of the various 'toxic' components in bile that can cause pancreatitis. Unconjugated bile salts (produced by bacteroides, *Streptococcus faecalis* and clostridia) and lysolecithin (produced by the pancreatic enzyme phospholipase A acting on bile lecithin) have both been shown to be damaging to the pancreas (Schmidt and Creutzfeldt, 1969). A mixture of *E. coli* and bile damages pancreatic ductal cells (Konok and Thompson, 1969), and this may be due to the bacteria converting bilirubin diglucuronide to free bilirubin or to some other unidentified compound (Banks, 1971).

Another theory on the relationship between acute cholecystitis and pancreatitis suggests that there is a retrograde spread of 'infection' by lymphatics, as this connection between the two organs has been demonstrated experimentally in the dog (Weiner et al., 1970).

Alcoholism: Kalant (1969) in his review of this topic has pointed out that there are several theories with little sound evidence to explain the known association between alcoholism and acute pancreatitis. One suggestion is that pancreatitis is caused by stimulation of pancreatic secretion coupled with spasm of the sphincter of Oddi (Schapiro et al., 1966). Secretion is stimulated first by the release of gastric acid which then promotes the release of secretin, and secondly by gastrin which acts directly on the pancreas in promoting secretion (Walton et al., 1962). There is some evidence that spasm of the sphincter of Oddi is produced by alcohol (Pirola and Davis, 1968). However, hypersecretion and ductal obstruction have been shown experimentally to produce only pancreatic oedema and not pancreatitis.

Another theory proposes an alteration in bile constituents by alcohol. Injection of bile into the pancreatic duct of the rat produces haemorrhagic pancreatitis. This reaction is more severe if the bile is obtained from animals intoxicated with alcohol (Gamklou and Edlund, 1966), but the nature of this 'alcoholic' bile is unclear.

The possibility of a cellular or a metabolic derangement of the acinar cells leading to pancreatitis has also been raised by several workers. Acinar cell changes of cytoplasmic degradation, mitochondrial swelling and lipid accumulation in rats on a chronic ethanol regimen have been demonstrated (Darle et al., 1970), whilst other work has shown an inhibition of ^{32}P uptake into pancreatic phospholipids in rats following long term ethanol ingestion, suggesting a metabolic defect (Orrego-Matte et al., 1969). Precisely how these changes may induce acute pancreatitis or make the gland more vulnerable is still not known.

It is of interest that Gillespie (1973) has recently found the incidence of alcoholism or a precipitating bout of drinking to be 23 per cent in a review of 93 cases of pancreatitis from the Edinburgh area. This figure is much higher than that quoted in other series from the United Kingdom and the author attributes this to either a concealment by the patient of his drinking habits or a higher rate of alcoholism in the Edinburgh area compared with the south of England.

Reflux of activated duodenal enzymes

McCutcheon (1968) has argued persuasively against the two older theories of the causation of pancreatitis, namely the theory of hypersecretion and ductal obstruction and the common channel theory of bile reflux. He has proposed instead the reflux of activated duodenal enzymes as the unifying concept in the initiation of acute pancreatitis.

The experimental evidence for duodenal reflux is based largely on the Pfeffer loop (Pfeffer et al., 1957). In this canine model a haemorrhagic pancreatitis can be induced regularly by the creation of a closed duodenal loop. If the pancreatic ducts are ligated the pancreas is protected, which suggests that reflux is the mechanism of action. This model has been compared with the human situation following partial gastrectomy. There was a much higher incidence of deaths from postoperative pancreatitis after a Polya gastrectomy (12 deaths in 1769 cases) compared with Billroth 1 gastrectomy (no deaths in 605 cases) in the series reported by Wallensten (1958). This is attributed by McCutcheon (1968) to the potential closed afferent loop in the Polya gastrectomy, and he quotes other clinical situations such as annular pancreas and duodenal diverticulum where a potential closed loop may be the cause of reflux and pancreatitis. The Pfeffer loop model can be modified in ways which suggest that the ensuing pancreatitis is caused by different mechanisms. If the bacterial flora within the loop is inhibited by topical antibiotics the incidence of haemorrhagic pancreatitis is reduced (Kune, 1968b; Williams and Byrne, 1968). Against this bacterial theory is the evidence that pancreatitis develops in germ-free dogs who have a Pfeffer loop (Nance and Cain, 1968), but it is possible that vascular compromise of the loop is of importance. In their original description of the experiment, Pfeffer et al. (1957) concluded that mucosal ischaemia in the loop was vital for the production of pancreatitis. This view has been further substantiated by experimental work in which the loop was decompressed; this prevented both mucosal ischaemia and the development of pancreatitis (Rosato et al., 1970). The conclusion from these experiments is that bacterial, ischaemic and enzymatic factors are contributing to the pancreatitis and that 'toxic' elements caused by the interaction of blood, bacteria and enzymes may be involved in different situations.

If McCutcheon's (1968) theory is correct then the function of the lower end of the pancreatic duct must be a critical factor in preventing pancreatitis. Damage or distortion of this sphincter is suggested in several situations. A gallstone impacted at the ampulla may produce a fixed dilatation of the duct, whilst the long arm of a T-tube may act as a splint and prevent closure of the duct. Alcoholic pancreatitis is explained by local damage to the papilla with oedema and incompetence. The possibility of vomiting induced by alcohol with a rise in duodenal pressure and pancreatic reflux is also suggested. With regard to the association between gallstones and pancreatitis, McCutcheon (1968) proposed the novel idea that both conditions arise as a result of duodenal reflux, and pancreatitis is only secondary to gallstones in the occasional case when a stone is impacted at the ampulla. He stated correctly in favour of his thesis that cholecystectomy and eradication of the biliary tract disease do not necessarily protect against further attacks of pancreatitis, but nevertheless his bald statement that 'there is no mechanism by which stones in the gall bladder can cause pancreatitis' may only be a reflection of our poor state of knowledge rather than a proved fact. The lymphatic connections between the two organs may be one such mechanism (Weiner et al., 1970).

Using another argument McCutcheon (1968) reasoned that sphincterotomy did not decrease the incidence of pancreatitis because reflux was continuing. It has, however, been shown that the much more effective operation of sphincteroplasty does reduce further attacks of pancreatitis (Jones et al., 1969) and so this argument is open to question.

At the moment the initiating role of the duodenal reflux must be considered a possibility in some cases of pancreatitis.

Pathogenesis

Once damage has occurred to the acinar cell there follows a series of changes within the gland which are poorly understood. Thus the role of the various pancreatic enzymes remains a matter of conjecture. Proteolytic enzymes have been recovered in an active form from pancreatic tissue in experimental acute pancreatitis, and trypsin and chymotrypsin can cause pancreatic inflammation when injected into the pancreatic duct. It is probable that the main action of trypsin is to activate the enzymes elastase and phospholipase A (Creutzfeldt and Schmidt, 1970) and possibly kallikrein. Elastase, which causes the dissolution of elastic fibres in blood vessels, appears important in the transition of oedematous to haemorrhagic pancreatitis, and a high level of elastase has been found in the pancreas of patients dying with haemorrhagic pancreatitis (Geokas et al., 1968). Phospholipase A is important in the development of pancreatic necrosis by its production of lysolecithin from bile lecithin. Higher levels of lysolecithin and lowered levels of lecithin have been found in glands that have undergone necrosis (Schmidt and Creutzfeldt, 1969). Ischaemia of the pancreas is a major factor in the development of haemorrhagic pancreatitis and necrosis. This may be due to several factors (Goodhead, 1969a): venous stasis (Anderson, 1963), release of vasotoxic substances (Anderson, 1961), the activation of pro-elastase (Geokas et al., 1968), the release of intracellular enzymes (Reid et al., 1958; Weissmann, 1965) and periacinar lymphatic occlusion (Anderson and Schiller, 1968). All may contribute to the vicious circle of vascular occlusion, thrombosis, increasing tissue anoxia and necrosis. A clear understanding of the processes leading to necrosis would give a basis for a rational prophylactic therapeutic regimen to be instituted.

The role of kallikrein in causing systemic hypotension has undergone critical study (Ofstad, 1970). It is known that pancreatic exudate contains strong kininogenase activity and that the plasma kinins released by kallikrein cause increased vascular permeability. Pancreatic exudate releases histamine from mast cells (Ofstad et al., 1969), and as this cannot be done by kallikrein some other factor may be present which contributes to the hypotension. Prostaglandin-like activity rises in the pancreatic venous effluent in experimental pancreatitis and high levels are found in the peritoneal exudate (Glazer and Bennett, 1974). The role of these substances in the hypotensive and pain responses remains to be elucidated.

Diagnosis

There is no completely reliable method of diagnosing acute pancreatitis apart from laparotomy. A classic clinical picture and a serum amylase above 1000 Somogyi units will usually give the diagnosis, but this picture is often confusing and may mimic several other abdominal crises such as acute cholecystitis, perforated or penetrating ulcer, bowel infarction and leaking or dissecting aneurysm. The laboratory aids to diagnosis are non-specific. A high serum amylase is often found in other conditions, and the level will also depend in part upon the timing of the blood sample. It is also a poor reflector of the severity of pancreatitis. The renal clearance of amylase increases in pancreatitis and the ratio of this clearance to creatinine clearance may be of diagnostic value (Levitt et al., 1969). Serum lipase levels were not considered helpful by Trapnell (1966) but may be of some value when improved methods of measurement are employed (Song et al., 1970). The level of serum catalase is elevated in pancreatitis and falls more slowly than serum amylase. Although this enzyme is not specific it has been recommended (Meszaros et al., 1973); these authors also described a new sensitive method of estimating catalase levels.

There are no specific clinical features of haemorrhagic as opposed to oedematous pancreatitis (Winstone, 1965); the presence of Grey-Turner's or Cullen's sign is a rare and late manifestation of the disease. Bruising in the flanks soon after the onset of acute abdominal pain should raise the possibility of a leaking abdominal aneurysm rather than pancreatitis.

The presence of methaemalbumin in the serum is not diagnostic of haemorrhagic pancreatitis and may occur in other acute conditions such as bowel strangulation, gastro-intestinal haemorrhage and soft tissue trauma (Battersby and Green, 1971). Furthermore, elevated levels are not always found in haemorrhagic pancreatitis. However, when the diagnosis has been established the plasma level of methaemalbumin is one of several parameters which are of importance in assessing and prognosticating about the course of the illness (Trapnell, 1966).

Clinical aspects

Clinical effects are systemic and local. The most important systemic effect is shock, which is the consequence of the loss of fluid into the retroperitoneal tissues and peritoneal exudate. Shock is probably increased by the release of vasoactive substances. Other systemic effects may include ileus, cardiorespiratory failure, renal failure, psychosis, coagulopathies and the metabolic changes of hypocalcaemia, hypomagnesaemia, hyperlipidaemia and hyperglycaemia.

The phase of cardiorespiratory failure may occur in the first 2 or 3 days; this syndrome appears to be less common in the United Kingdom than in other countries, a fact attributed to differences in the aetiological background of the disease. Hypoxaemia (Po_2 below 75 mm Hg) was found in 58 per cent of 40 unselected patients with early pancreatitis (Ranson et al., 1973). These workers and others (Kellum et al., 1972) stressed the insidious nature and seriousness of this complication. The diagnosis at an early stage can only be made by blood gas analysis. The autopsy findings in the lungs are of congestion and diffuse areas of microscopic atelectasis (Gliedman et al., 1970). The cause of these changes is not known although circulating lecithinase has been incriminated; elevated levels of serum lecithinase have been found in patients with pancreatitis (Zieve and Vogel, 1960) and this is known to cause pulmonary surfactant changes when infused into dogs (Morgan et al., 1965). The presence of pleural effusions, a high diaphragm and increased metabolic demands will also contribute to the respiratory embarrassment. It is probable that the pulmonary changes in pancreatitis are non-specific and are similar to those found in a variety of other shock states and injuries (Blaisdell and Schlobohm, 1973). From a clinical point of view an increased awareness of the respiratory problem should lead to routine arterial blood gas analysis. A patient who develops a psychotic state is likely to be hypoxaemic, and delirium tremens should only be considered when blood gases are found to be normal.

Renal failure, defined as a rise in blood urea to above 100 mg/100 ml or when there were post-mortem changes of acute tubular necrosis, was found in 15 per cent of 41 patients treated by Gordon and Calne (1972). They suggested that the cause of the failure may be more complex than simple hypotension and fluid loss and postulated that toxic products of pancreatic autodigestion are contributing to the response.

There have been recent suggestions that the hypocalcaemic response in acute pancreatitis may be due to more than the deposition of calcium in fat necrosis. One theory is that glucagon, released in acute pancreatitis (Banks and Janowitz, 1969), may stimulate the release of thyrocalcitonin which would cause inhibition of bone resorption and hypocalcaemia (Avioli et al., 1969). Another theory suggested that the hypocalcaemia is secondary to hypomagnesaemia (Muldowney et al., 1970) which makes the bone refractory to the action of parathormone. The cause and precise incidence of hypomagnesaemia in pancreatitis are not known. More information is required before the cause of the hypocalcaemia can be determined but it seems clear that a low level of serum calcium (below 7·5 mg/100 ml) is associated with a bad prognosis (Trapnell, 1966).

The local effects of the disease in the abdomen are due to the peritoneal exudate and include damage to surrounding structures such as the spleen, intestines and major blood vessels. Jaundice due to local oedema or an associated gallstone is not uncommon. Pancreatic ascites may develop owing to rupture of a pancreatic duct or pseudocyst, and is characterized by an exudate with a high amylase content.

The later complications of pancreatitis have been well described by Trapnell (1971) and include abscess, pseudocyst, haematemesis, duodenal obstruction and colonic necrosis (Katz et al., 1974).

In the early stages of the disease the clinician is faced with the difficulty of recognizing the patient with incipient or established haemorrhagic or necrotizing pancreatitis. Continuing severe pain, shock, cyanosis, paralytic ileus, toxaemia, respiratory and renal failure all suggest severe underlying pancreatitis. Prolongation of the ileus was considered by Trapnell (1966) to be a particularly ominous clinical sign, as was the later development of Grey-Turner's sign. The laboratory investigations of a high WBC, low serum calcium and arterial Po_2 and a high serum methaemalbumin will also indicate fulminating pancreatitis.

Management

The mortality of acute pancreatitis has fallen since the turn of the century, but there has not been a major improvement in recent years. Specific treatment is not available and improvement in outcome has been due to an understanding and correction of the associated systemic derangements that arise. Many forms of drug treatment have been used, but there are constantly recurring problems in their assessment. First, it is impossible to extrapolate the experimental animal responses to the human situation, and secondly the variable clinical course of pancreatitis makes controlled trials difficult.

Systemic treatment

1. *Shock*: The shock state in pancreatitis is comparable to that in a large burn, but, unlike that situation, there is no rapid way of calculating fluid replacement. Losses of up to 40 per cent of the circulating blood volume may occur and replacement therapy must be closely controlled by central venous pressure, blood pressure, urine output, haematocrit and electrolytes. Large volumes of fluid, electrolytes, plasma expanders and blood may be required. The adequacy of fluid replacement is of critical importance in overcoming the early mortality (Kune, 1968a). Despite active treatment a refractory state of shock may supervene, suggesting that vasoactive substances are contributing to the response.
2. *Renal failure*: Oliguric renal failure should be treated by restoration of the circulating volume and, if necessary, by dialysis. Peritoneal dialysis is particularly effective (Wall, 1965), presumably because of the added effect of the peritoneal lavage; haemodialysis is more efficient, but there are the attendant risks of electrolyte disequilibration and haemorrhage due to the heparin in these sick patients (Gordon and Calne, 1972).
3. *Cardiorespiratory failure*: Increasing respiratory difficulties, cyanosis or psychosis should be assessed promptly by repeated measurement of arterial blood gases. Oxygen at high flows should be commenced (Ranson et al., 1973), and in extreme cases of respiratory failure and hypoxia, tracheostomy and positive pressure respiration are indicated (Louw et al., 1967). Salt-poor albumin and intensive diuretic therapy may also help to improve arterial P_{O_2} (Kellum et al., 1972). Cardiac insufficiency, indicated by a rising venous pressure and poor organ perfusion, requires digitalization and possibly isoprenaline (Louw et al., 1967). Pleural effusions should be tapped.
4. *Metabolic*: Hypocalcaemia is treated with 10 per cent calcium gluconate given intravenously, and hypomagnesaemia is treated with 25 per cent magnesium sulphate by intramuscular injection.
5. *Diabetes*: Occasionally an acute transient hyperglycaemia develops. This usually subsides without insulin which is only indicated in persistent hyperglycaemia or ketosis.

Local non-surgical treatment

The principles in treating the pancreas are to promote pancreatic blood flow (and hence reduce the incidence of early necrosis), to suppress pancreatic secretion (and thus reduce further enzymatic damage), to counteract vasoactive enzymes produced by the pancreas and to combat local infective changes.

1. *Promotion of pancreatic blood flow*: There is strong experimental evidence that promoting pancreatic blood flow will reduce the severity of pancreatitis (Goodhead, 1969a). Low molecular weight dextran has been recommended to prevent occlusion within the pancreatic microcirculation (Carey, 1970; Goodhead, 1969b), but other authors have suggested that local oedema and ascites are increased by this therapy (Anderson and Lewis, 1965). However, these latter studies did show experimental improvement with dextran 75 000. Heparin and fibrinolysin have also been used experimentally in dogs to promote blood flow in pancreatitis, with improved results (Wright and Goodhead, 1970). However, careful assessment must be made before they are accepted as therapy in the human situation, where anticoagulants must be used with caution in situations of intra-abdominal inflammation.

Adrenocortical steroids have been advocated in the treatment of acute pancreatitis (Kaplan et al., 1964) and they may act by promoting pancreatic blood flow. However, other authors have not found benefit (Kune, 1968a), and the fact that steroids may induce pancreatitis (Nelp, 1961) makes their use in therapy somewhat illogical. There are no properly controlled trials to prove the point either way and it appears that most clinicians reserve steroids for cases in extremis.

2. *Suppression of pancreatic secretion*: There is little information available on the degree of secretion taking place during an attack of pancreatitis, but it seems logical to suppress secretion if possible. Several methods have been used, including nasogastric suction, anticholinergics, acetazolamide, propylthiouracil and recently glucagon (Knight et al., 1971). None of these treatments has been shown to be of value. Anticholinergics did not have benefit in Trapnell's uncontrolled series (Trapnell, 1966), and although glucagon looks promising from a recent report (Condon et al., 1973), with a low mortality of 2 deaths in the 30 patients treated, the significance of these figures cannot be assessed because it is not known whether patients were in their first or subsequent attacks and this is known to affect the outcome (Trapnell, 1966).
3. *Inhibition of vasoactive enzymes*: Aprotinin (Trasylol) has been used for many years in the treatment of acute pancreatitis; it works as a trypsin and kallikrein inhibitor and in experimental preparations can ameliorate attacks of acute pancreatitis (Kune, 1968b). In clinical practice there has been less convincing evidence of its efficacy, possibly because of low dose and delay in commencing treatment. Early controlled trials with small numbers of patients failed to show any benefit from the drug (Skyring et al., 1965; Baden et al., 1969), but many other reports based on clinical impressions suggested that improvement was obtained. There has been a recent report of a strictly controlled double blind trial with Trasylol (Trapnell et al., 1974), using an initial dose of 200 000 units and then 200 000 units 6-hourly intravenously for 5 days. The patients admitted to

this trial either did not have an overt cause of their pancreatitis or were known to have gallbladder disease. There was a significant reduction in mortality in the 53 patients receiving the drug (4 deaths, 7·5 per cent) compared with the 52 patients receiving the placebo (13 deaths, 25 per cent), and in particular the high mortality in elderly patients was reduced. This work has reawakened the waning surgical interest in Trasylol and is of further value in that the authors have classified the severity of illness of their patients with pancreatitis by careful criteria which should serve as a model for any future clinical trials of drug therapy.

4. *Infection*: The value of prophylactic antibiotics in the early treatment of fulminating pancreatitis is open to question. There are impressions from some authors that septic complications are reduced by broad spectrum antibiotics (Louw et al., 1967; Kune, 1968a), but it appears that the outcome of the attack is not affected by this therapy (Trapnell, 1966).

Surgical treatment

The traditional view of surgical intervention in acute pancreatitis was that it should be avoided (Bowers, 1956; Thompson and Derrick, 1957), but recently there has been a trend to a more active surgical approach. The accepted indications for laparotomy are in cases of diagnostic uncertainty and pancreatic trauma. In these situations the surgeon's duty is clear. What is not so clear is the timing of laparotomy in 'proved' pancreatitis which is failing to respond to non-operative treatment, and the right course to pursue when the abdomen has been opened. Some authors (Anderson, 1965; Zimberg, 1968) have recommended surgery after 6–12 hours, if the patient has failed to improve, but extended the time to 24 hours if an underlying biliary tract condition is suspected. It remains to be seen whether this more active approach is the correct one, but there is certainly no evidence from the literature that early laparotomy is harmful (Trapnell, 1966; Louw et al., 1967; Kune, 1968a; Diaco et al., 1969). However, the incidence of burst abdomen is high—9 per cent in Trapnell's (1972) series.

If laparotomy has been performed the policy followed will depend on the findings. In cases of necrotizing pancreatitis the sloughing retroperitoneal mass should be sucked out and drained adequately. The splenic and hepatic flexures should be mobilized as there may be a retroperitoneal extension of the slough behind the colon and also into the root of the small bowel mesentery. Total pancreatectomy would be logical in severe haemorrhagic pancreatitis with its high mortality and has been carried out with success (Watts, 1963), but this prospect will daunt most surgeons and will be impossible when there is total necrosis. If haemorrhagic pancreatitis is discovered peritoneal lavage and effective sump drainage should be instituted (Waterman et al., 1968). There are sound theoretical reasons for removing the peritoneal exudate and continuing with postoperative peritoneal lavage. The experimental and clinical evidence in favour of lavage has recently been presented (Rosato et al., 1973). Peritoneal lavage can be performed in the non-operative case by the percutaneous placement of catheters, and this has been strongly recommended (Bolooki and Gliedman, 1968). The addition of Trasylol to the lavage fluid may be helpful (Wall, 1965), whilst hypothermic lavage has its advocates (Rasmussen, 1967). The final assessment of the value of these therapies must await adequate clinical trials.

The management of the infected and obstructed biliary tract associated with acute pancreatitis is uncertain; the evidence is unconvincing for or against cholecystectomy or early decompression by cholecystostomy or T-tube drainage of the bile duct. Decompression by cholecystostomy is simple and safe but the presence of stones within the duct coupled with jaundice may call for exploration and T-tube drainage. An early direct approach to a stone impacted at the ampulla of Vater is not recommended (Anderson, 1965; Louw et al., 1967; Trapnell, 1972) because of the technical problems and possibility of causing further pancreatic damage. However, Salzmann and Bartlett (1963) reported 6 patients who were successfully treated by transduodenal sphincterotomy during intractable attacks of acute pancreatitis, and so there may be a place for this operation on occasions. However, there is no question of the need for surgery in the later complications of abscess and duodenal obstruction (Trapnell, 1971). Although pseudocysts do resolve spontaneously, surgical drainage is usually indicated and this subject has been reviewed by Simpson and Srivastava (1973).

Conclusion

Until there is a fuller understanding of the pathogenesis of acute pancreatitis a rational prophylactic and therapeutic regimen cannot be instigated. At present there is little evidence in favour of the various drugs and operations recommended. In future all treatments should be scientifically assessed before gaining acceptance, and it is encouraging that multicentre trials organized on a national scale are under way in the United Kingdom.

Acknowledgements

I should like to thank Professor H. A. F. Dudley and Mr J. Trapnell for their helpful advice in the preparation of this manuscript.

Plasma catecholamines in severely injured patients: a prospective study on 45 patients with multiple injuries

A. JÄÄTTELÄ, A. ALHO, V. AVIKAINEN, E. KARAHARJU, J. KATAJA,
M. LAHDENSUU, P. LEPISTÖ, P. ROKKANEN AND T. TERVO*

SUMMARY

Plasma catecholamine levels were studied in 45 severely injured patients for 8 days after the trauma. Sixteen of the patients were classified as critically injured and 29 as seriously injured.

The total plasma catecholamine values of the whole group immediately after the injury were almost twice as high as the eighth day reference values and remained significantly higher than these values for 6 hours after the trauma. On admission both the plasma adrenaline and noradrenaline levels were elevated. The plasma adrenaline levels on admission correlated with the blood volume replacement which was required within the first 6 hours.

The plasma noradrenaline levels in the critically injured group were significantly higher throughout the observation period than in the seriously injured group. A corresponding difference was observed in the plasma adrenaline concentrations only during the first 12 hours.

The results showed that strong stimulation of the sympathetic nervous system occurs in severely injured patients. Factors stimulating the sympathetic nervous system apparently included hypovolaemia, tissue hypoxia, acidosis and the pain produced by the truama and therapeutic measures.

SEVERAL factors that have been found individually to cause stimulation of the sympathetic nervous system are associated with severe trauma; these include pain, fear, haemorrhage, tissue damage, etc. (Walker et al., 1959). A similar effect is exerted by the different anaesthetic procedures (Price, 1957; Black et al., 1969) and surgical interventions (Nikki et al., 1972) which are necessary in the case of severely injured patients.

Our knowledge of the total stimulation of the sympathetic nervous system caused by various factors in traumatized patients is minimal. Measurement of the sympathetic activity is difficult. The urinary catecholamine content has been considered to give a reliable overall idea of the long term activity of the sympathetic nervous system (Crout, 1961). Post-traumatic elevation of the level of urinary catecholamines and their metabolites has been established (Coward and Smith, 1966). Urinary catecholamine measurements are, however, incapable of recording the rapid variations characteristic of sympathetic activity. On the other hand, this can be done by measuring the plasma catecholamine concentrations (Carruthers et al., 1970).

The purpose of this study was to elucidate the activity of the sympathetic nervous system and the role of the factors influencing it by measuring the plasma catecholamine levels for 8 days following injury.

Patients and methods

Forty-five consecutive patients with multiple injuries who had been admitted to the intensive care unit of University Central Hospital, Helsinki, were investigated. The criterion for investigation was that the patient was admitted within 2 hours of the trauma and that the research bed was free. A traffic accident was the cause of injury in 35 cases. The patients with two or more critical injuries were graded as critically injured (*Table I*); the mortality in this group was 9 out of 16. All 29 patients survived in the group graded as seriously injured.

The main treatment for shock was compensation of hypovolaemia. Treatment was started with an infusion of 1000 ml of dextran with saline (Macrodex) and continued with balanced saline solutions up to 1000 ml and blood transfusions. No sympathomimetic or sympatholytic agents were used in the treatment of

Table I: AGE, SEX AND INJURIES OF THE PRESENT SERIES

	Critically injured group	Seriously injured group
Number of patients:	16	29
Age (yr, mean±s.e.):	39±3·8	34±2·8
Sex (male : female):	8/8	22/7

	Degree of severity*		Degree of severity	
Site of trauma	Critical	Moderate	Critical	Moderate

shock. During the first 24 hours 14 patients were given 30 mg/kg of methylprednisone, divided into three doses, at intervals of 8 hours. Acidosis was corrected if necessary with 7·5 per cent sodium bicarbonate. When the patient was considered incapable of adequate respiration on the basis of the clinical status and the arterial blood gas analysis, volume-controlled respirator treatment was instituted.

Major operations were performed under nitrous oxide–oxygen relaxant anaesthesia (*Table II*). The adjuvants used when necessary were fentanyl and droperidole. Pethidine and atropine were used for premedication.

Systolic and diastolic blood pressure (by the indirect method) and heart rate were recorded at least once every hour. On admission a catheter was inserted in the superior vena cava. The central venous pressure was not always measured until 6 hours after the accident.

Blood samples for catecholamine measurements were taken through the central venous catheter at 0–2, 6, 12, 24 hours and 2 days after injury. In addition, a reference sample was taken 8 days after the accident. Samples of arterial blood were taken for the determination of pH, standard bicarbonate, BE, $P\mathrm{CO}_2$ and $P\mathrm{O}_2$ at the same time as the specimens for catecholamine determination. Among other values, the haematocrit and eosinophil levels were determined.

The material was treated by automatic data processing (Computer Centre, University of Helsinki). The t-test, χ^2 test and Fisher test were performed.

Table II: MAJOR SURGICAL PROCEDURES

Surgical procedures	Critically injured group: Within 6 hours	Critically injured group: After 6 hours	Seriously injured group: Within 6 hours	Seriously injured group: After 6 hours
Laparotomy	3	3	0	0
Thoractomy	0	2	0	1
Thoracolaparotomy	2	0	0	0
Thoracotomy or laparotomy and other procedures	1	0	3	1
Internal fixation*	2	2	6	2
Total	8	7	9	4

* The internal fixations performed within 6 hours were: 1 fixed angle nailing of the femur, 4 intramedullary nailings of the femur, 2 intramedullary nailings of the tibia and 1 plating of the dorsal spine. The later internal fixations were: 1 intramedullary nailing, 1 fixed angle nailing and 1 L-plating of the femur and 1 intramedullary nailing of the femur and tibia.

Catecholamine determinations

The technique used for the quantitative determination of adrenaline and noradrenaline in the plasma was based on the principles described by Vendsalu (1960). Each determination required an 18-ml sample of blood. Perchloric acid was used in the deproteinization of the plasma. Dowex 50-X4 columns (200–400 mesh, dimensions 28 mm² × 20 mm) in hydrogen form were used for purification of the extracts. The elution was performed with N hydrochloric acid. The adrenaline and noradrenaline in the eluate were determined spectrophotofluorometrically (Aminco-Bowman) after oxidation with potassium ferrocyanide and subsequent rearrangement to adrenolutine and noradrenolutine. The fluorescences of the lutines of adrenaline and noradrenaline were measured at different wavelengths. Faded blanks and reagent blanks were calculated as described by Vendsalu (1960). Internal standards were used by adding known amounts of adrenaline or noradrenaline or both to the plasma samples. Recovery by the method was 78 ± 4 (mean ± s.e.) per cent of adrenaline and 73 ± 4 per cent of noradrenaline. Duplicate extractions on plasma samples gave results that varied no more than 10 per cent.

Results

The means of the systolic blood pressure, heart rate, haematocrit and the cumulative volume compensation for the whole series at the corresponding intervals are presented in *Table III*. On admission the arterial pH (7·34 ± 0·01), standard bicarbonate (19·4 ± 0·6 mmol/l) and $P\mathrm{CO}_2$ (35·4 ± 1·1 mm Hg) values showed a tendency towards metabolic acidosis which had been corrected by 6 hours. The $P\mathrm{O}_2$ was below 75 mm Hg on admission in 17 patients, at 6 hours in 10 patients and at 12 hours in 6 patients.

The means of the total plasma catecholamine, adrenaline and noradrenaline levels for the whole series are shown in *Fig.* 1. The highest value of the total plasma catecholamines (2·03 ± 0·33 μg/l) was recorded on admission. It was significantly higher ($P < 0·001$) than the 8-day value (1·09 ± 0·09 μg/l). Subsequently, the total plasma catecholamine level fell evenly and did not differ significantly ($P < 0·02$) from the reference value except at 6 hours. The plasma adrenaline content was highest on admission (0·95 ± 0·28 μg/l), had dropped to 0·61 ± 0·18 μg/l by 6 hours and the reference value at 8 days was 0·38 ± 0·06 μg/l. The noradrenaline content both on admission (1·08 ± 0·12 μg/l) and at 6 hours (1·14 ± 0·16 μg/l)

Table III: SYSTOLIC BLOOD PRESSURE, HEART RATE, HAEMATOCRIT AND THE CUMULATIVE BLOOD VOLUME REPLACEMENT AFTER INJURY

Time interval from accident	Systolic blood pressure (mm Hg)	Heart rate (per minute)	Haematocrit	Volume compensation (litres)
Admission	95±6	107±3	—	—
2 Hours	120±6	106±3	0·40±0·01	1·0±0·2
6 Hours	128±3	110±3	—	4·0±0·5
12 Hours	129±3	103±4	0·36±0·01	4·8±0·5
24 Hours	131±5	106±3	0·35±0·01	5·6±0·6
2 Days	143±4	100±3	0·33±0·01	—
8 Days	141±4	102±3	0·38±0·01	—

Results given as means ± s.e.

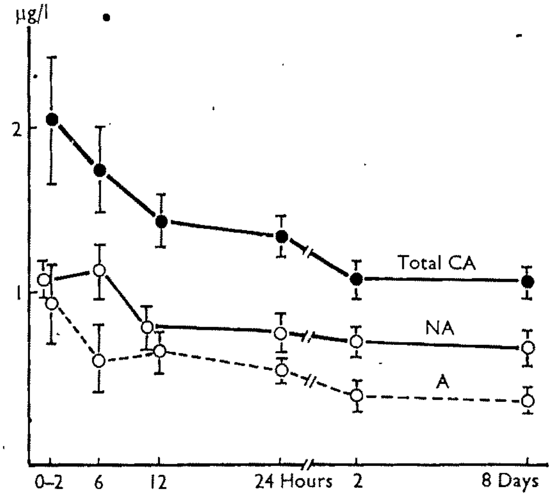

Fig. 1. Total plasma catecholamines (total CA), adrenaline (A) and noradrenaline (NA) of the whole series at different times after injury (mean and s.e.).

was significantly higher ($P<0{\cdot}02$ and $P<0{\cdot}05$ respectively) than the reference value (0·71 ± 0·09 µg/l).

On admission the mean systolic blood pressure in the critically injured group was 78 ± 10 mm Hg and in the seriously injured group 105 ± 7 mm Hg ($P<0{\cdot}02$). At 6 hours the corresponding values were 123 ± 9 mm Hg and 130 ± 6 mm Hg and the difference between the groups had thus disappeared. The mean heart rate value on admission in the critically injured group was 117 ± 4/minute and in the seriously injured group 102 ± 4/minute ($P<0{\cdot}01$). After 48 hours no differences in blood pressure or heart rate were recorded between the groups.

The volumes of blood given to the critically and the severely injured in the course of the first 24 hours are shown in *Fig.* 2. The amount of blood (6·2 ± 0·9 litres) given to the critically injured during the first 6 hours was significantly greater ($P<0{\cdot}001$) than that (2·7 ± 0·4 litres) received by the severely injured.

There were no significant differences in the haematocrit values or the central venous pressures between the

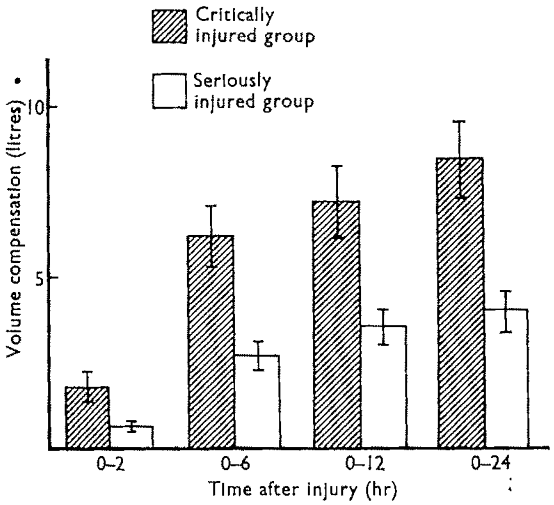

Fig. 2. Cumulative compensation of hypovolaemia in the critically injured and seriously injured groups during the first 24 hours after injury (mean and s.e.).

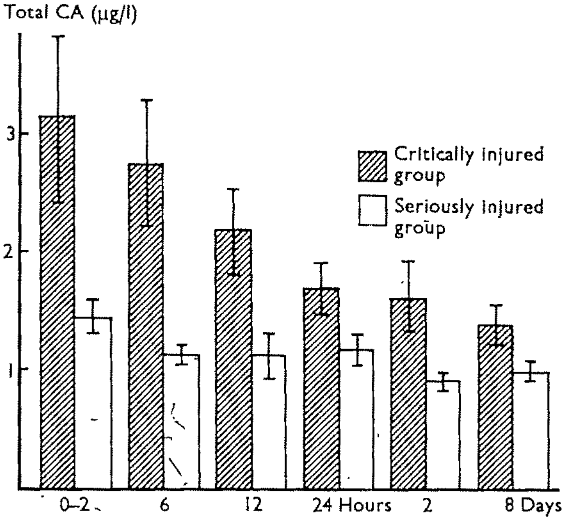

Fig. 3. Total plasma catecholamines (total CA) in the critically injured and seriously injured groups at different times after injury (mean and s.e.).

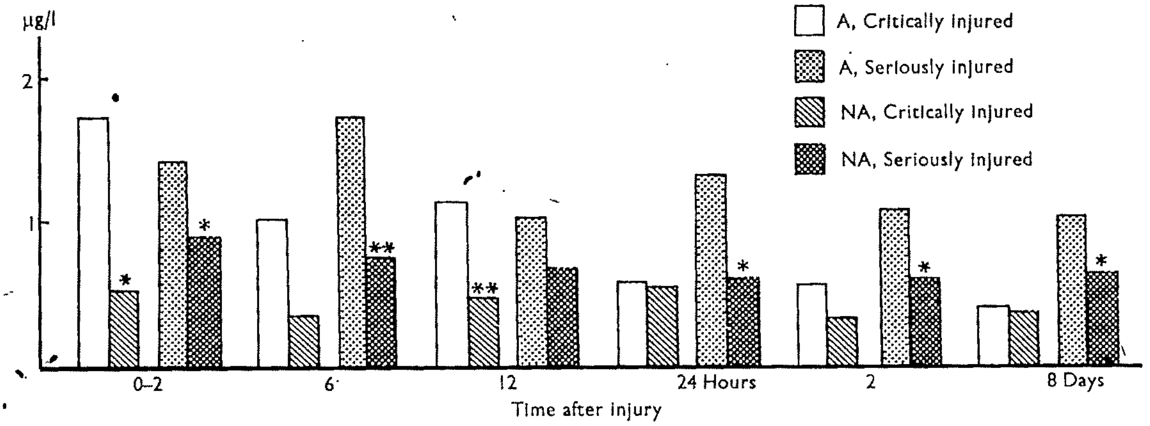

Fig. 4. Plasma adrenaline (A) and noradrenaline (NA) in the critically injured and seriously injured groups at different times after injury (mean and s.e.). * $P<0{\cdot}05$. ** $P<0{\cdot}01$.

groups. On admission metabolic acidosis was more pronounced in the critically than in the seriously injured group. During treatment this difference disappeared at 12 hours. On admission Po_2 was below 75 mm Hg in 8 critically injured patients and in 9 patients of the seriously injured group.

The total plasma catecholamine level on admission was 3·14 ± 0·83 μg/l in the critically injured group and 1·43 ± 0·12 μg/l in the seriously injured group ($P < 0·01$) (*Fig.* 3). The difference between the total catecholamines of the groups later decreased evenly but was statistically significant throughout the 8-day period. The adrenaline and noradrenaline contents of the plasma were similarly significantly higher ($P < 0·05$) on admission in the critically than in the severely injured group (*Fig.* 4). There were no significant inter-group differences in the adrenaline levels after 12 hours ($P < 0·01$), but the differences in the noradrenaline levels persisted.

The blood volume transfused within the first 6 hours correlated with the plasma adrenaline levels recorded on admission ($P < 0·05$). No corresponding correlation was established for noradrenaline.

The plasma catecholamine levels of the patients given methylprednisone did not differ from those of the patients not given this drug. Patients receiving no methylprednisone showed no correlation between the eosinophil cell count and plasma catecholamine level.

The plasma adrenaline levels of 9 patients who died from their injuries were significantly higher than the levels of the survivors ($P < 0·05$). No such differences were observed in the noradrenaline levels.

Discussion

'Many attempts have been made to measure adrenaline and noradrenaline levels in blood after injury but no consistent changes have been detected' (Johnston, 1972). Differing from this conclusion, we observed in a preliminary report (Jäättelä, 1972b) and in the present study significantly elevated post-traumatic plasma catecholamine levels in patients with multiple injuries. The elevation of the plasma adrenaline concentration was of short duration, but the noradrenaline concentration at 8 days was still almost double the value recorded for healthy persons by the same method (Jäättelä, 1972a). The elevation of the plasma catecholamine levels was significantly higher in the critically injured than in the severely injured group. The main reason for the divergence of these results from earlier observations is probably the great severity of the injuries suffered by the patients in the present series.

Noradrenaline acts as a transmitter substance in the peripheral nerve endings of the sympathetic nervous system. The adrenal medulla, which is comparable functionally with sympathetic ganglions, secretes both adrenaline and noradrenaline (Axelrod and Weinshilboum, 1972). The stimulation of the sympathetic nervous system in severely injured patients is obviously produced by several factors. Animal experiments have shown that profuse blood loss alone greatly increases the plasma catecholamines (Watts, 1956; Lillehei et al., 1964). The increase is believed to take place partly via the volume receptor, pressor-receptor and chemoreceptor systems (Berne and Levy, 1967; Ganong, 1973), and partly as a result of tissue hypoxia and acidosis (Woods et al., 1956). Young and Gray (1956) found that trauma alone, without external blood loss, produced an increase in the plasma catecholamine concentrations of rat.

In the emergency treatment of severe trauma, operations under general anaesthesia are often necessary. Both the operative stress (Gött and Klensch, 1970; Nikki et al., 1972) and the different methods of anaesthesia (Price, 1957; Black et al., 1969) have been found to produce an increase in plasma catecholamines. Other therapeutic interventions, such as tracheal suction, exert a stimulating effect on the sympathetic nervous system (Jäättelä and Heinonen, 1971). Eight of 17 primary operative procedures (within 6 hours) in the present series were done for operative fixation of fractures. Of course, priority was always given to more vital injuries. Our experience is that patients with multiple injuries are easier to nurse and they feel better with their fractures stably fixed than in plaster or on traction. This may be important in diminishing the stimuli for catecholamine secretion.

In the present study the highest plasma catecholamine levels were recorded immediately after the trauma, when hypovolaemia, hypoxaemia, acidosis and pain were at their most intense. The plasma catecholamine levels during anaesthesia and operation were lower than the initial values, which shows that the catecholamine-releasing effect of these factors was slight compared with that of hypovolaemia. The fact that the plasma noradrenaline level remained higher in the critically injured than in severely injured patients at 8 days was probably due to various stress factors.

The plasma adrenaline but not the noradrenaline levels on admission correlated with the blood volume transfused within the first 6 hours. Lillehei et al. (1964) observed in their experiments with dogs that at the beginning of haemorrhage the plasma adrenaline concentration increased steeply and proportionately to the volume deficit and blood pressure fall.

The haematocrit values decreased in the whole series until the second day, despite the fact that the patients were already haemodynamically stable at the end of the first day. This is accounted for by slow haemodilution. Concurrently with this there was a decrease in catecholamine excretion, leading in turn to dilatation of the vascular bed (Simmons et al., 1969). This obviously also contributed to the decrease in the haematocrit values at 2 days.

Our findings indicate that multiple injuries in man initially produce a pronounced increase in both the adrenaline and the noradrenaline levels of plasma. This is partly attributable to the increased excretion by the adrenal medulla caused by hypovolaemia, and partly to the release of noradrenaline from the sympathetic nerve endings caused by tissue hypoxia and acidosis. After correction of these causative factors, the stimulating effect of pain and various other stress factors on the sympathetic nervous system continues, as is suggested by the persistingly high plasma noradrenaline levels, particularly in critically injured patients.

these patients with varicose veins had not been examined with Doppler ultrasound, an error in view of his past history of deep vein thrombosis. Of the other 3 cases, one presented 2 days after negative Doppler examination, and in another fatal pulmonary embolism occurred on the fourteenth postoperative day. Doppler examination was normal on the ninth postoperative day and as the patient was fully ambulant no further examination was performed. In the fourth patient iliofemoral venous thrombosis of the left leg presented with gross swelling only 12 hours after a normal Doppler examination.

3. *The temperature chart*

Six of the 8 patients had low grade pyrexia in the postoperative period but most had some inflammatory focus to account for it (*Table IV*). In only 2 could it be attributed solely to the venous thrombosis. In one, calf tenderness suggested calf vein thrombosis which was confirmed by phlebography. In the second, several days' unexplained pyrexia was followed by sudden swelling of the whole of the leg (*Fig*. 2). In retrospect, this unexplained pyrexia should have been further investigated by phlebography. In 2 patients who developed deep vein thrombosis there was no postoperative pyrexia and one of these suffered a fatal pulmonary embolism (*Fig*. 3).

Discussion

This study has confirmed that Doppler ultrasound can detect thrombotic occlusions of the main vessels of the thigh and pelvis. It also confirms that in general surgical practice the patients most at risk are those over 35 years of age undergoing major abdominal operations and those with a past history of deep vein thrombosis. Screening and prophylaxis can reasonably be confined to this group.

Venous thromboses confined to the calf were not detected directly by ultrasound but 2 were detected by tenderness on Doppler examination.

In this series Doppler ultrasound has proved quite unreliable in detecting early non-occlusive iliac vein thrombosis. This situation might be improved by examining patients from the fourth postoperative day until discharge and by examining daily rather than on alternate days. However, one iliac vein thrombosis presented with leg swelling only 12 hours after a negative Doppler examination. It seems likely that these thrombi develop gradually over several days. Neither swelling nor positive Doppler findings will occur until total or near total occlusion of the vein

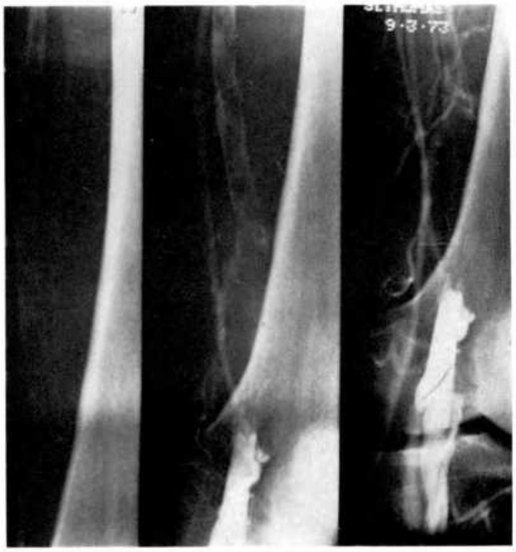

Fig. 1. Phlebogram showing femoral vein thrombosis in a 37-year-old man. This was initially detected by Doppler ultrasound.

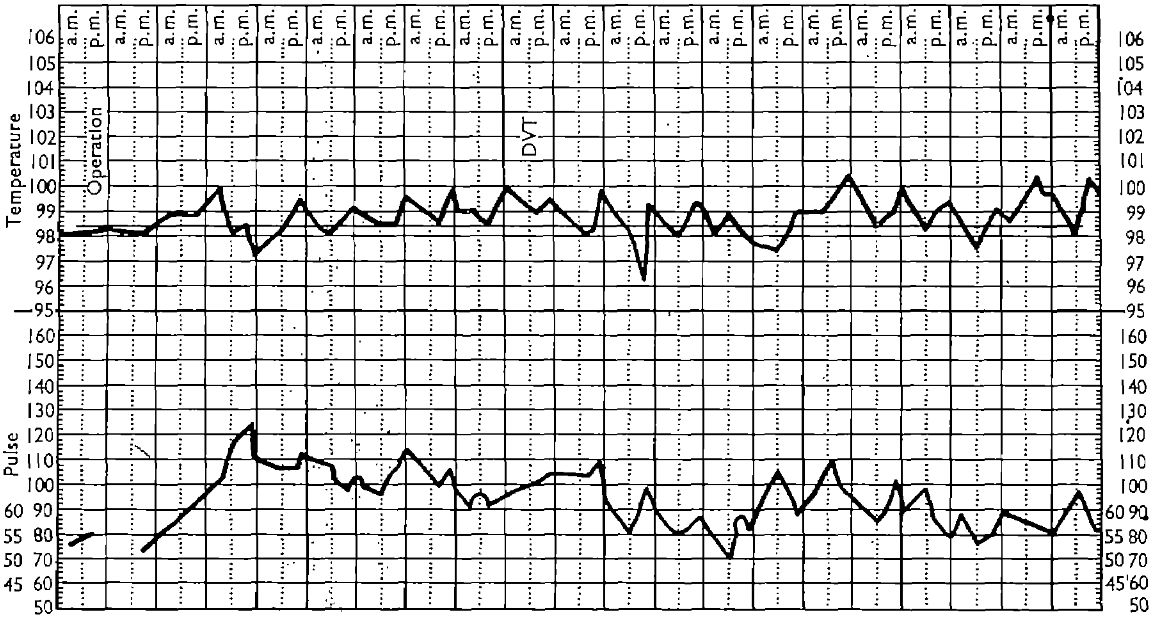

Fig. 2. Low grade pyrexia indicating early iliac vein thrombosis in a 52-year-old woman.

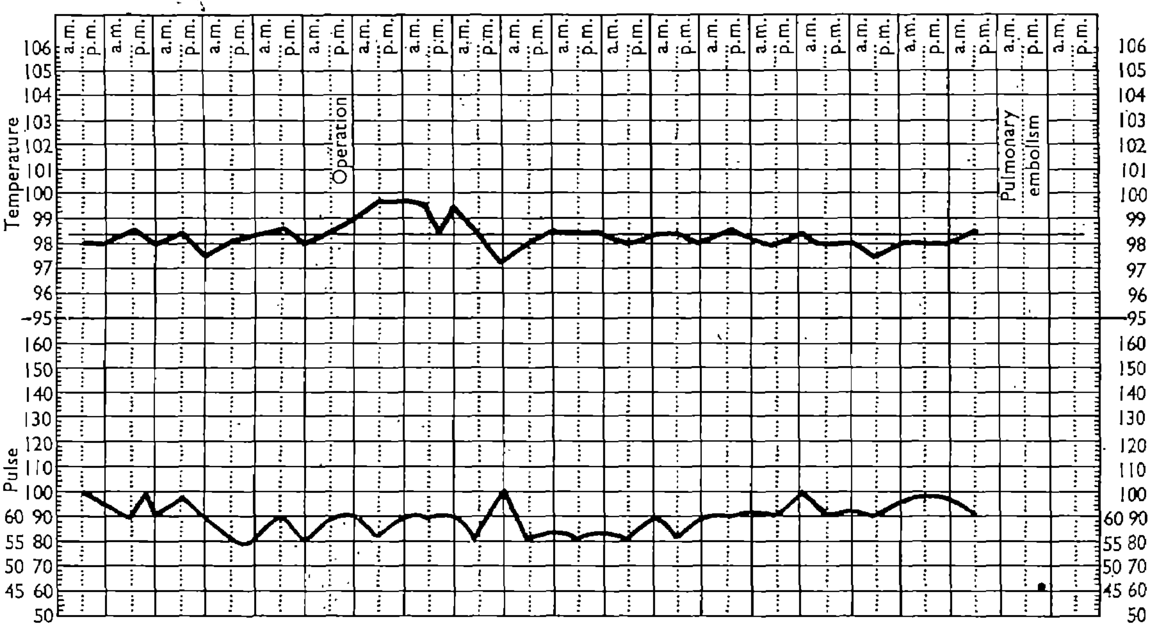

Fig. 3. Normal temperature chart of the 42-year old woman who died from massive pulmonary embolism.

lumen has taken place. This disadvantage seriously limits the value of Doppler ultrasound as a screening technique. ^{125}I-fibrinogen uptake is even less able to detect iliac vein thromboses which are the chief source of major embolism.

Study of the temperature chart has proved of little value. While an unexplained postoperative pyrexia may indicate a deep vein thrombosis requiring further investigation with phlebography, some patients with major thrombosis have no elevation of temperature, and other patients at risk have some septic focus to account for the pyrexia.

The inadequacy of available monitoring techniques emphasizes the importance of establishing simple and reliable methods of prophylaxis.

Surgical management and problems of heart pacing*

J. BORRIE AND I. LICHTER†

SUMMARY

Experience with 40 patients and 150 pacemakers is reviewed. In 13 patients the initial pacing was by epicardial electrodes and in 27 by transvenous catheter electrodes. When epicardial systems were used, two electrodes were always fixed to the heart, the additional electrode being provided for temporary pacing and as a spare in case of future need. The battery unit was usually buried behind the rectus abdominis muscle. Vacuum drainage of the pacemaker pocket was used and was considered helpful in avoiding some complications.

The right cephalic vein was preferred for transvenous pacing but existing venous abnormalities sometimes required use of the external jugular vein. Five patients had epicardial systems changed to transvenous ones, and in 5 the reverse procedure was needed. Pacemaker battery problems included inadequate soft tissue protection for the unit, epoxy resin fracture, titanium case leak and problems relating to design change and the special needs for overseas travel. While the danger from diathermy and radiofrequency is now recognized, similar dangers exist for those paced by 'demand' units in large electromagnetic fields.

BETWEEN 1962 and 1973 cardiac pacing was instituted in 40 patients at Dunedin, and in that time 150 pacemaker units were used. The pacemakers used were at first Elema-Schonander units from Sweden and more recently Telectronics from Australia. On one occasion an Electodyne pacemaker was inserted. This paper reviews that experience with emphasis on the surgical and technical aspects.

Patients

There were 27 males and 13 females. The age distribution is shown in *Table I*.

Table I: AGE DISTRIBUTION OF THE PRESENT SERIES

Age (yr):	No. of patients:
31–40	3
41–50	1
51–60	4
61–70	15
71–80	17
Total	40

Thirty-five of the 40 were paced for heart block, and 5 patients for 'sick sinus syndrome'. In 13 patients the initial pacing was by epicardial electrodes and in 27 by transvenous catheter electrodes.

In 5 patients a change from epicardial to transvenous pacing was later needed; in another 5 there was a change from transvenous to epicardial pacing.

Epicardial pacing

Our first patient had his pacemaker inserted in September 1962 when aged 66 (Borrie and Lichter, 1964). He is still alive and well 13 years and 11 pacemakers later.

Operative approach

The incision for epicardial pacing has usually been a left anterior fifth intercostal space thoracotomy, which gives ready access to the pericardial cavity. Two platinum electrode buttons are sewn on to the myocardium, usually of the right and left ventricles. Two sutures fix the platinum button, and a third steadies the adjacent electrode, so that good contact is maintained. Even when using unipolar pacemakers it has been our policy to insert two platinum electrodes, one for pacing and the other as a spare in case of electrode fracture, or for connecting to a sterile wire from a temporary external unit during pacemaker change.

A trans-sternal incision was used by one of us (J. B.) in a patient who had had a right pneumonectomy 15 years earlier. An attempt at placing a transvenous electrode had failed and it was considered inadvisable to disturb the left lung by a left thoracotomy. The xiphoid and lower sternum were therefore split vertically and access was enhanced by an approach between the xiphisternal origins of the diaphragm, thus enabling the electrodes to be sutured to the inferior surface of the heart.

Pacemaker site

The most favoured site for burying the epicardial pacemaker unit has been in the left rectus sheath, behind the rectus abdominis muscle. A transverse skin incision at umbilical level has proved satisfactory, followed by a vertical rectus sheath incision. If necessary, the incision may be extended into the adjoining rectus muscle sheath to place the pacemaker with its long axis across the midline. However, when using the rectus sheath it is necessary to avoid the lower quarter where only transversalis fascia constitutes its posterior layer. A pacemaker placed in this site later prolapsed into the pelvis.

While it is convenient to fashion a pocket in the axilla, breast or the fat of the ventral abdominal wall, in the long term problems have arisen at these sites so that we now favour the deeper site in the right or left rectus sheath. The electrodes are brought down into the pocket by means of a long metal guide, passed from the pocket to the left pleural cavity. Loops of electrode are left at both the cardiac and pacemaker ends of the system, being coiled outside the pericardium above, and behind the pacemaker below.

Vacuum drainage

We have found vacuum drainage of the pacemaker pocket an aid to rapid healing. Up to 25 ml of tissue fluid have on occasion drained daily for up to 10 days after operation.

Wound resuture

In 2 patients pacemaker pocket wounds have required early resuture—once when skin sutures were mistakenly removed on the fifth postoperative day, and once on the tenth postoperative day following suture removal in a patient whose wound had been closed without vacuum drainage. Both responded to immediate secondary suture.

Transvenous pacing

Our cardiologists first used temporary catheter pacing electrodes in 1964, and permanent implantable transvenous electrodes in 1967.

Vein catheterization

In catheterizing veins a small disposable plastic vein retractor has proved invaluable, as has a simple binocular loupe that allows normal or magnified vision. The image intensifier is always available. We have found that the Elema-Schonander catheter electrodes require support from a cardiac catheter guide to help easy placement in contact with the right ventricular myocardium.

In earlier patients the right or left external jugular vein was used, placement of the electrode being aided initially by standard screening X-ray equipment, and later by an image intensifier. The electrode was usually placed behind the clavicle using Semb pneumonectomy forceps. Later an appropriately shaped steel hook was designed to facilitate this manœuvre. The electrode was then brought down to the rectus sheath and buried behind the right rectus abdominis muscle.

As the external jugular vein is comparatively superficial, it is not surprising that 3 patients, by constantly scratching their cervical scars, in time caused wound breakdown, wire prolapse and even wire fracture. Thus, although the external jugular vein has been used fourteen times, the cephalic vein is now favoured and has been used thirteen times. It is preferred because it is more deeply placed and disturbance by the patient is less likely. Further, it avoids the step of passing the electrode *behind* the clavicle.

Anatomical variations of both the external jugular and cephalic veins have at times dictated which vein was used.

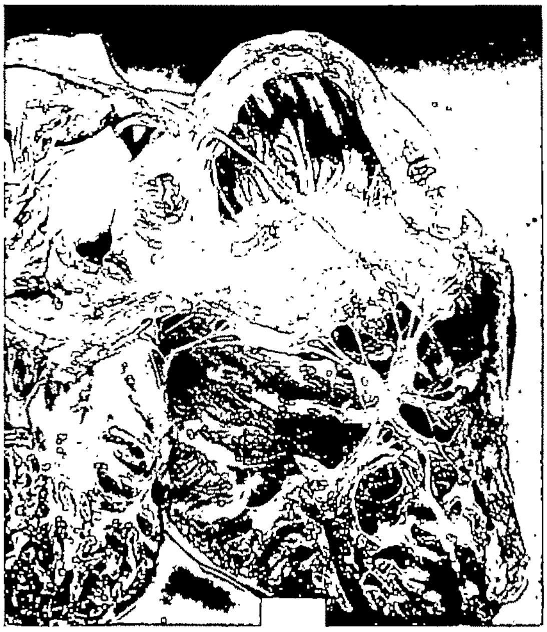

Fig. 1. View of left leaf of the tricuspid valve of a patient who had been successfully paced for 15 months, and who came to autopsy with aortic stenosis. The pacemaker electrode had passed between two chordae tendineae without causing chordal rupture.

Electrode placement problems

In 2 patients who came to autopsy an opportunity was provided for studying the transvenous catheter electrode *in situ*. In both the electrodes were firmly embedded in the right ventricular myocardium. In one the electrode had passed between the chordae tendineae of the tricuspid valve and had been there for 15 months without causing chordal rupture (*Fig.* 1).

Electrode displacement problems

In 5 patients displacement of the catheter electrode into the right atrium occurred, with loss of heart pacing. In one of these the electrode lay near the diaphragm and caused persistent hiccups. In another the electrode slipped from the heart into the liver. The time lapse between implantation of these transvenous electrodes to loss of 'pacing contact' varied from 2 months to 15 months.

Change from transvenous to epicardial pacing

In the 5 patients with persistent displacement of the transvenous electrode a change was made to an epicardial system.

Change from epicardial to transvenous pacing

Five of the 13 epicardial systems were changed to transvenous systems for the following reasons: fractured electrode, 1 patient; sinuses associated with pacemaker, 2 patients; sinuses associated with electrodes, 2 patients. The sinuses occurred usually after more than 5 pacemaker unit changes, and indicate a hazard to be faced where battery life is of the order of just 2 years.

Electrode problems

These have involved:

a. Skin breakdown as a result of scratching the supraclavicular electrodes at the site of entry into the external jugular vein. This problem has not arisen with cephalic vein electrodes.

b. Sinuses at other sites due to 'surfacing' of the electrode on ribs.

c. Lead fractures, either near the pacemaker unit or, if transvenous, near the site of entry into the vein.

Pacemaker unit problems

Trauma to pacemaker pocket

One patient with a right rectus sheath pacemaker connected to a transvenous system for 'sick sinus syndrome' felt so fit postoperatively that, when showing his biceps to his neighbour while lawnmowing, he was struck on the pacemaker by the mower. He did not report the accident but 'poulticed' the unit to 'draw it to the surface'. The result was a haematoma sinus that, despite resiting the unit, did not heal. Because infection later tracked up to his neck producing an abscess at the entry point of the electrode into the right external jugular vein, the system had to be completely removed. Eighteen months after this excision he has had no further attacks of bradycardia, nor has a further unit been inserted.

Patients are advised to protect the pacemaker from body blows and are urged to report early any change in relation to the pacemaker site. Problems encountered have included the development of fluid around the pacemaker and inflammation or erosion of the overlying skin.

'Runaway' pacemakers

On two occasions a pacemaker suddenly increased its rate beyond 200 pulses per minute. This is a surgical emergency demanding immediate removal of the pacemaker. In an early model pacemaker, where there were bursts of 300 pulses per minute, the epoxy resin had fractured, producing a short circuit. In another instance a Telectronic unit developed a leak in the titanium case, producing a short circuit.

Manufacturing problems

'Takeovers' of pacemaker companies have led to inability to match existing implanted systems with the 'new product', and in our experience these unfortunate patients have had to have an entirely new system implanted in a new site.

Overseas travel

It has been possible to send paced university staff on sabbatical leave even to Japan or India—where replacement costs could be high—by having the patient take on loan a sterile unit supplied through the Regional Hospital Board. The patient must take letters signed by the surgeon to cover customs problems. Surgical and cardiological details should be supplied for those who may be consulted abroad.

Radiofrequency, diathermy and pacemakers

In a previous paper we described the hazards of radiofrequency and the use of diathermy which can trigger certain pacemakers into bursts of activity to produce ventricular fibrillation (Lichter et al., 1965). Since our experiments and reports of this hazard it has become Health Department policy both in the United Kingdom and in New Zealand to warn against the use of diathermy in the presence of any cardiac pacemaker.

However, similar dangers still exist in heavy industry using high frequency currents producing large electromagnetic fields, e.g. aluminium smelters, where some 'demand pacemakers' can be adversely affected. Patients should be warned of this, especially if they go sightseeing through heavy industry.

Nuclear-powered pacemakers

We have not yet had occasion to insert a nuclear-powered unit, but can see a very real place for such units, especially in patients whose life expectancy with pacemaker support is more than 10 years, as in a younger patient with 'sick sinus syndrome'. We have noticed that with the present battery units, the more frequent the change, the greater is the risk from infection or delayed healing of the fibrous tissue that inevitably increases with each pacemaker change.

In conclusion, pacemakers have proved life-saving devices for those with heart block, allowing normal activity up to 12 years from the first implanting. Occasionally their management may be punctuated by episodes that demand tedious and exacting attention from cardiologists, surgeons, technicians and theatre staff, and considerable patience and understanding from the patient. Strict care with basic surgical principles reduces these hazards to a minimum.

Acknowledgements

This paper records one facet of teamwork in which the cardiologists involved have been Professor J. D. Hunter, Professor T. V. O'Donnell, Dr Amarassingham and Dr Norma Restieaux. Their help is gratefully acknowledged, as is that of Mr N. Miller, Mr E. Cooper and Mr L. Wong for electronic supervision and Miss N. Richardson for secretarial assistance.

Postoperative problems and management after hepatic resection for blunt injury to the liver

T. VAJRABUKKA, A. L. BLOOM, M. SUSSMAN, C. B. WOOD AND L. H. BLUMGART*

SUMMARY

The postoperative problems and management of 8 patients following right hepatic lobectomy for blunt liver injury are discussed. Multiple injury and in particular chest injury are of importance. Respiratory distress may be insidious in onset and must be anticipated. Most patients require at least temporary positive pressure ventilation.

Liver regeneration is rapid and histological evidence of regenerative hyperplasia is present within 3 days of injury.

Hypoglycaemia of a degree sufficient to threaten life may occur postoperatively, particularly in the first 48 hours. Jaundice may be a worrying postoperative feature, but the use of T-tube drainage after hepatic lobectomy will enable any possible extrahepatic obstruction to be excluded. Hypoproteinaemia and hypo-albuminaemia occur in the immediate postoperative period, and recovery rapidly follows the peak period of regenerative activity of the liver. Normal levels are regained by the fourth to sixth postoperative weeks.

Prophylactic antibiotics have no place in the postoperative management of blunt liver injury.

Haemorrhagic diathesis is common after hepatic resection and is of a complex nature. Intravascular coagulation may occur and factor V deficiency is common. The mainstay of treatment is transfusion of fresh blood.

THE mortality for blunt liver injuries has decreased from 60 per cent (Mikesky et al., 1956; Foster et al., 1968) to 30 per cent or less (Little and Williams, 1969; Walt, 1969; Blumgart and Vajrabukka, 1972; Donovan et al., 1973). The improvement has been the result of better techniques of resuscitation, adequate blood transfusion and improved management of the more extensive injuries. Several authors have drawn attention to the danger of gauze packing for large destructive wounds of the liver (Crosthwait et al., 1962; Hanna et al., 1965; McClelland and Shires, 1965), and hepatic resection has been accepted in the management of very extensive blunt liver injuries (Walt, 1969; Balasegaram, 1970; Little, 1971; Blumgart and Vajrabukka, 1972). This more agressive surgical approach with resection of large segments of damaged tissue has been based on an appreciation of the extraordinary regenerative capacity of the liver (Weinbren, 1959; McDermott et al., 1963; McDermott, 1970; Blumgart et al., 1971).

The postoperative period following major hepatic resection can be complicated by metabolic disturbances which, if not anticipated and recognized, can be life-threatening (Pack and Molander, 1960; McDermott et al., 1963; Almersjö et al., 1969; Aronsen et al., 1969). These metabolic disturbances, together with problems arising as a direct result of multiple injury, massive blood transfusion and infection, form a complex clinical problem.

This paper reports experience of the postoperative management and problems encountered following right hepatic lobectomy for blunt liver injury carried out in 8 previously healthy patients.

Patients

The essential features of the 8 cases are summarized in *Table I.* All sustained their injuries as a result of road traffic accidents. Two were injured in crushing accidents, 1 pedestrian was hit by a passing car, 1 fell from the back of a moving milk van and the other 3 were the drivers of either a motor-cycle or a car. All were young (aged between 9 and 39 years) and all had been in previously good health.

Five cases were operated on within 3 hours of injury although in one of these cases (*Case* 1) a first operation entailed simple suturing of the liver, and right hepatic lobectomy had to be carried out for recurrent haemorrhage 10 hours later. This patient has been previously reported (Taylor and Blumgart, 1971). In the remaining 3 cases there was a longer delay between the time of injury and the time of operation. One patient (*Case* 4) was operated on 12 hours after admission, the definitive signs of intra-abdominal haemorrhage being absent until this time. One patient was not operated on until the sixth hour after injury as a result of delay in transport to hospital. The remaining patient was admitted to another hospital with multiple injuries and was transferred to our care 72 hours after the accident, deeply jaundiced, anuric and with obvious signs of peritoneal irritation (*Case* 6).

In each instance the hepatic injury was extensive and, apart from minor lacerations to the left lobe, was confined to the right lobe of the liver. The parenchymal destruction in each case (*Fig.* 1) could not be dealt with adequately by any other means than formal hepatic resection, the indications for which

Table I: DETAILS OF THE PRESENT SERIES

Case	Sex	Age	Causes	Associated injury	Time from accident to operation	Units of blood transfused	Postoperative complications	Weight of liver resected (g)	Remarks
1. J. F.*	M	21	Crushed by a lorry	Flail chest, bilateral pneumo-haemothoraces, concussion	3 h+second operation 10 h after first	18	Respiratory difficulty, tracheostomy and PPV, pneumonia, empyema, wound infection, haemorrhagic diathesis, early hypoglycaemia (mild), terminal renal shutdown	Not recorded	Died 10 days after operation. Post-mortem showed extensive lung contusion, bronchopneumonia, oedematous pancreas with necrotic foci
2. M. R.	M	22	Motor cyclist in collision with a tree	Concussion, fracture of right forearm	3 h	20	Respiratory difficulty, tracheostomy and PPV, haemorrhagic diathesis, pneumonia, infected T-tube bile, subphrenic abscess	650	Survived
3. S.O.*	F	9	Pedestrian hit by a car	Concussion, ruptured spleen	2 h	12	Severe hypoglycaemia, haemorrhagic diathesis, pneumonia, biliary leakage around the choledochotomy site, wound infection, subphrenic abscess	375	Survived
4. S. D.*	M	13	Fell off a milk van	Nil	12 h	4	Transient respiratory difficulty, intermittent hypoglycaemic episodes during subsequent 2 weeks (mild), pneumonia, T-tube bile infection, septicaemia, peritonitis	449	Survived
5. D.O.*	M	23	Crushed by a bus	Multiple long bone and pelvic fractures, ruptured right diaphragm, tear of second part of duodenum, compression necrosis of ascending colon	3 h	22	Haemorrhagic diathesis, right haemothorax	745	Died 10 hours after operation. Post-mortem showed, tear in azygos vein, haemorrhagic necrosis of both adrenals, bronchopneumonia
6. J. M.	M	28	Hit by a car (transferred from another hospital)	Fractures of right tibia, fibula and forearm, ruptured right kidney, concussion	72 h	30	Respiratory difficulty, tracheostomy and PPV, acute renal failure, infected T-tube bile, septicaemia, haemorrhagic diathesis, intermittent hypoglycaemic episodes during the next 3 weeks (mild), acute pancreatitis, pneumonia, empyema, wound infection	1045	Died
7. R. B.	M	19	Car in collision	Fractures of right humerus, contusion of right lung, laceration of right thigh	2 h	24	Transient respiratory difficulty, pneumonia, wound infection, subphrenic abscess	970	Survived
8. M. D.	F	39	Car in collision	Fractured ribs, cervical vertebral body C5 and pelvic rami, lung contusion, concussion	4–5 h	19	Transient respiratory difficulty, haemorrhagic diathesis	800	Survived

* Included in previous reports (Taylor and Blumgart, 1971; Blumgart and Vajrabukka, 1972).
PPV, Positive pressure ventilation.

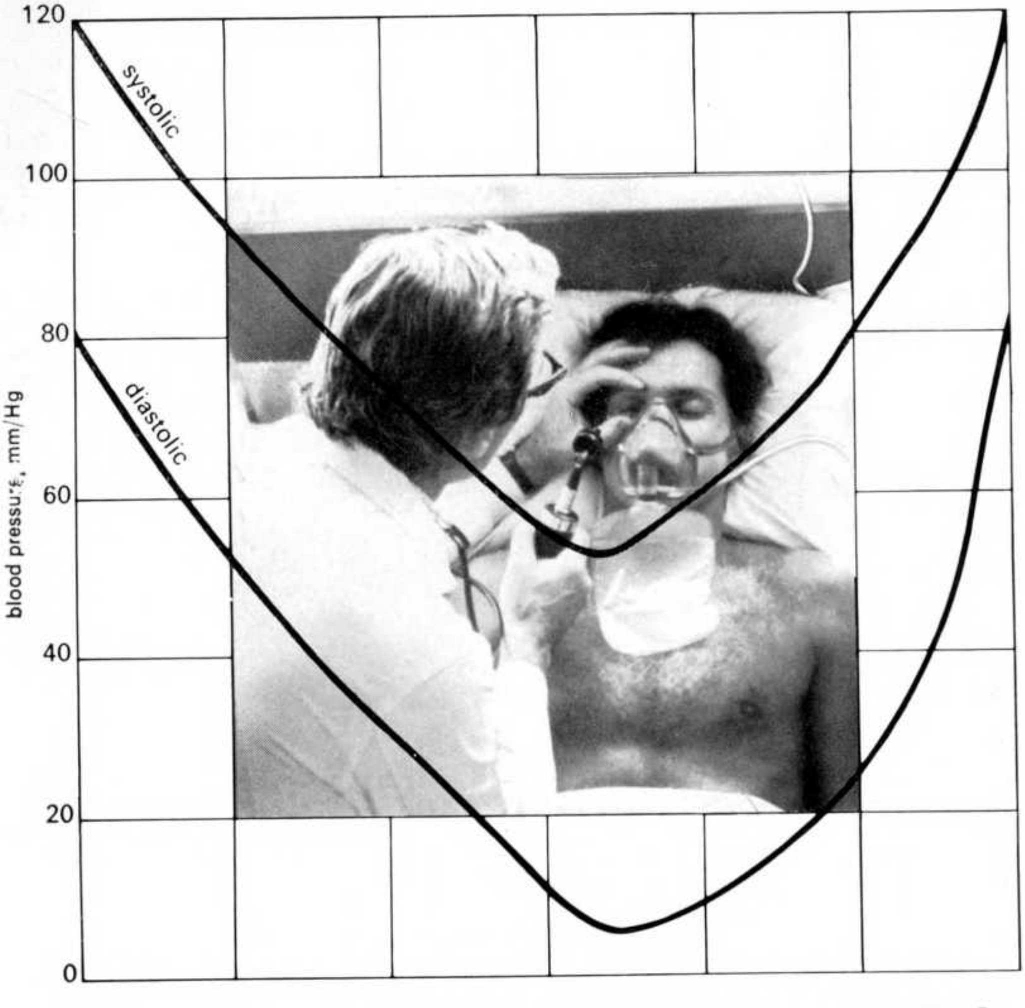
Now paediatrics gets the Seward treatment.

At Seward, we believe that instruments for paediatric surgery are every bit as important as adult instruments.

That's why we spent a long time developing and perfecting our own paediatric range – and we're grateful for the co-operation of so many children's hospitals, paediatric departments and consultants.

Now the range is complete – 580 fine quality stainless steel instruments. Including many which have never before been modified for paediatric use. And some entirely new instruments developed in the Seward workshop.

Survival rate in shock can be increased with massive doses of corticosteroids



Injection DECADRON® Shock-Pak

Dexamethasone sodium phosphate/MSD

20 mg/ml (new strength)

In severe shock, treatment with Injection 'Decadron' Shock-Pak is an adjunct to, and not a substitute for, specific or supportive measures that the patient may require, e.g. restoration of circulating blood volume, correction of fluid and electrolyte balance, oxygen, surgical measures, and antibiotics.

Supplied in 5 ml ampoules containing per ml, dexamethasone sodium phosphate equivalent to 20 mg dexamethasone. Detailed information is available to physicians on request. ® denotes registered trademark.

have been previously described (Blumgart and Vajrabukka, 1972; Blumgart, 1973). All 8 patients underwent right hepatic lobectomy via a right thoraco-abdominal incision, the technique employed being essentially that described by Quattlebaum and Quattlebaum (1959) and by Lloyd-Davies and Angell (1957). All were managed with postoperative chest drains, drainage to the right subhepatic space and T-tube drainage as suggested by Merendino et al. (1963).

Postoperative management

The patients were returned to the ward and the need for blood transfusion was monitored according to the blood pressure, pulse rate and central venous pressure recordings. An intravenous infusion of 1 litre of normal saline and 2 litres of 5 per cent dextrose saline solution for 24 hours formed the basis of intravenous therapy. Oral fluids were prescribed in the early postoperative period and the nasogastric tube was aspirated hourly. The volume of drainage from the chest drain, the subdiaphragmatic drain(s) and the T-tube was monitored, as was the urinary output.

All except one patient had superficial flesh wounds and in addition to wound débridement each received a booster dose of tetanus toxoid. All but one of the patients received an intramuscular course of ampicillin 250 mg 6-hourly. Vitamin K was administered in a dose of 10–20 mg intramuscularly daily.

Frequent estimations were made of the haemoglobin, packed cell volume, blood glucose, serum amylase and serum electrolytes. Liver function was assessed daily by recording changes in the serum proteins, serum bilirubin, alkaline phosphatase and serum transaminases.

Regular estimations were made of the blood gases and the acid-base status of the patients. Endotracheal intubation, tracheostomy and positive pressure ventilation (PPV) were used when indicated.

Organ:	Frequency:
Spleen	1
Kidney	1
Duodenum	1
Ascending colon	1
Diaphragm	1
Azygos vein	1
Lungs	3*

* One was bilateral.

A full haematological survey for clotting factors was undertaken in all the patients, and if possible, this was done before transfusion was commenced. The haematological studies were repeated daily for as long as necessary.

Samples for bacteriological examination were taken daily from the sputum, tracheostomy site and from all the drainage tubes; other sites were sampled if this was thought necessary.

Postoperative problems and complications

The postoperative problems encountered can be conveniently reported and discussed under four main headings.

1. *Problems arising as a result of multiple injury*

Patients with liver injury seldom have rupture of the liver as an isolated lesion. In a series of 20 cases previously reported by us (Blumgart and Vajrabukka, 1972) the liver alone was injured in only 2.

Of the 8 patients in this report, only one had injury to the liver alone. The others had damage to one or more organs (*Table II*). The frequency of injury to other abdominal organs, particularly in the upper abdomen, makes careful exploration mandatory. The spleen should be examined in all cases, and indeed was found to be ruptured in one of our patients. Injuries to the duodenum and pancreas may easily be missed at laparotomy and must be sought deliberately.

It is of interest that concussion was common and occurred in 5 cases. In 2 (*Cases* 2 and 3) the period of unconsciousness lasted longer than 2 hours with some degree of post-traumatic amnesia after recovery. There were no associated skull fractures in any case.

Musculoskeletal injuries were common (*Table I*), and it is of particular interest that 4 patients had associated fractures of the right upper arm or of the ribs on the right side, and in 1 patient there was an extension 'whip-lash' fracture of the body of C5. The management of these musculoskeletal injuries took second place to the treatment of the liver injuries in our patients. Fractures were temporarily splinted and reduction immobilization carried out at the end of the abdominal operation. Lengthy orthopaedic manipulations were not undertaken and plaster casts were applied in such a way as not to interfere with the process of monitoring the patient's vital signs. Definitive orthopaedic treatment, if required, was carried out electively at a later date. It is of interest that the pattern of skeletal injury, both to the upper limb on the right and to the ribs on the right side, suggested direct trauma to the posterolateral margin of the chest wall as the mechanism of hepatic injury.

The most serious postoperative problem encountered as a result of multiple injury involved damage to the chest. Early postoperative respiratory difficulty was common. Although this was anticipated in 3 cases (*Cases* 1, 7 and 8) with severe injuries, altogether 7 of the 8 patients required endotracheal intubation and positive pressure ventilation. Even such methods were insufficient and in 3 patients tracheostomy proved necessary. It is clearly evident that it was not only the effects of mechanical disruption of the chest alone (e.g. flail chest, pneumothorax) which were life-threatening but also the more subtle complications of blood and sputum retention. Although none of our patients had direct injury to the heart or thoracic aorta, these possibilities must be borne in mind. The signs of traumatic rupture of the thoracic aorta in particular may not be seen until many days after initial injury. A high index of suspicion, repeated examination of the patient and repeated good quality chest X-ray films, including aortography in cases of real doubt, will identify many of these patients in time for definitive treatment.

2. *Problems of postoperative infection*

Infective complications are an ever present danger after hepatic resection. Though many surgeons recommend the prophylactic administration of antibiotics after liver resection (Walt, 1969; Donovan et al., 1973) this practice requires re-examination.

It is clear from our data that infective complications were common despite the use of prophylactic antibiotics. Indeed, the only case (*Case* 8) who did not develop a serious clinical infection (other than a urinary tract infection) was the only patient who did not have antibiotic prophylaxis.

Apart from bronchopneumonia diagnosed at autopsy in 3 cases, there were infections at 22 separate sites in this series of patients (*Table III*). The initial infections were commonly due to single organisms (72 per cent) and the rest (28 per cent) due to at least two organisms. *Escherichia coli* was the most common organism isolated and was involved in over half (56 per cent) of the infected sites. In particular, *E. coli* was found in relation to drains and catheters. In only 2 cases were the first organisms isolated sensitive to the prophylactic antibiotics, but the flora rapidly changed and resistant organisms appeared. In addition, many organisms appeared at the sites where originally only one had been involved. Many of these were highly resistant to antibiotics. Five patients acquired *Candida albicans* infection and in 4 of these more than one site was involved, but in no case was specific therapy required. In 5 patients with infection at more than one site the same organism or organisms were responsible for the infection. This fact, together with the staggered appearance of infection, suggests that the infection spreads from one site to another, and this has obvious implications for nursing procedures.

A positive blood culture was obtained in both patients from whom specimens were taken in the early postoperative period. Infection of T-tube bile was always accompanied by other infection. In one case a subphrenic abscess developed and in another a patient developed localized peritoneal irritation following removal of the T-tube. In one of these patients the infection spread to a pleural effusion.

3. *Haemorrhagic diathesis*

Haemorrhagic diathesis is a well-recognized problem after hepatic resection (Nilehn et al., 1967; Aronsen et al., 1969; Walt, 1969; Little, 1971; Taylor and Blumgart, 1971; Blumgart and Vajrabukka, 1972). For this reason blood coagulation surveys were carried out, if possible on admission, and before transfusion was commenced. The studies were repeated as frequently as necessary.

Method: Platelet counts, prothrombin times, kaolin cephalin times, thrombin clotting times, fibrinogen titres and tests for fibrinolysis were always performed immediately after venepuncture. Coagulation factor assays were usually performed soon after venepuncture but occasionally on samples of plasma stored at −30°C for a maximum of 3 days.

Platelet counts were performed on a Coulter Model F electronic counter, prothrombin times and thrombin clotting times were performed as described by Biggs and Macfarlane (1962) and kaolin cephalin clotting times by the method of Proctor and Rappaport (1961). Fibrinogen titres were measured by the method of Sharp et al. (1958). Using this method the normal fibrinogen level was 1/32 to 1/128 which is approximately equivalent to 200–500 mg/100 ml (Giddings and Bloom, 1971). Fibrinogen levels below 100 mg/100 ml were indicated by a titre below 1/16. Clottable fibrinogen was measured by the method described by Varley (1967). Increased fibrinolysis was demonstrated by a dilute clot lysis method (Giddings and Bloom, 1971). Fibrin degradation products (FDP) were measured by the Wellcome Laboratories modifications of the method of Merskey et al. (1966). Factor VIII assays were performed by the method of

‡ Serum amylase 2000 units.

§ Platelet transfusion given.

Poll and Robinson (1959), factor V assays by the method of Speer and Borges (1962), factor IX assays as described by Hardisty and Ingram (1965) and factor II assays by the two-stage procedure (Biggs and Macfarlane, 1962). Factor X assay and an assay sensitive to deficiency of either factor VII or X were performed by the method of Denson (1961) using Russel viper venom–cephalin mixture for the former assay and saline extract of brain for the latter.

Results: Coagulation defects occurred in all the patients and were sometimes of a complex nature. The results obtained on the days when the coagulation defects were most marked are summarized in *Table IV*. The causes of the coagulation defects may be multiple and those which may have been responsible in our patients are shown in *Table V*. In only 2 cases could the cause be confidently established. One of these cases (*Case 2*) showed classic features of the defibrination syndrome with a preoperative low platelet count, low fibrinogen level and prolonged prothrombin time, thrombin time and kaolin cephalin clotting time (*Table VI*). This patient received 20 units of blood

before and during surgery, 10 of which were fresh blood. The abnormalities were shown to be rapidly corrected following evacuation of the haematoma, surgical repair and transfusion of fresh blood. There was transient mild thrombocytopenia on the third and fourth postoperative days, the cause of which was not determined but could have been due to loss of transfused platelets.

In another case (*Case* 3) liver impairment alone could account for most of the abnormalities found (*Table VII*). This patient received 9 units of stored blood during surgery and 3 units of fresh blood during the next 24 hours. The studies showed only minor deficiencies of platelets and coagulation factors. On the day following surgery the main defects were prolonged prothrombin times, which were corrected by addition of normal serum, and increased fibrinolysis consistent with hepatic impairment. The raised FDP could have been the effect of the increased fibrinolytic activity or due to absorption from the haematoma and there was no firm evidence of intravascular coagulation.

The findings in the other 5 cases were not amenable to such simple explanations and it is probable that they resulted from several causes (*Table V*). The presence of thrombocytopenia of greater or lesser degree, deficiency of factor V and sometimes prolonged thrombin times or raised levels of FDP suggested some degree of intravascular coagulation, but this was by no means certain in every case.

The low levels of factor V were particularly striking and would be consistent with impaired liver synthesis. Indeed, we have since noted similar deficiencies of factor V following extended right hepatic lobectomy for carcinoma of the liver. In one case (*Case* 6) intravascular coagulation (*Table VIII*) occurred as a terminal event in association with acute pancreatitis. This patient had received 10 units of stored blood soon after injury and 20 units (4 fresh) during operation. The coagulation studies obtained during and immediately after hepatectomy were all within the normal range. Postoperatively there was a fall in the platelet count and a rise of FDP. This could have been due to intravascular coagulation but may have been the result of transfusion and the absorption of FDP from haematoma. On the other hand, terminally there was a profound fall in the platelet count with a prolonged thrombin clotting time, abnormal prothrombin and kaolin cephalin times and raised FDP. These changes were associated with marked elevation of the serum amylase (2000 Somogyi units) and were consistent with intravascular coagulation complicating pancreatitis.

The common occurrence of thrombocytopenia, possibly due to transfusion or intravascular coagulation, and the low levels of factor V, probably the result of defective liver production, were particularly noteworthy.

4. *Liver regeneration and associated metabolic problems*

The liver exhibits a remarkable regenerative capacity after major resection. In man this regenerative activity commences soon after operation and progresses

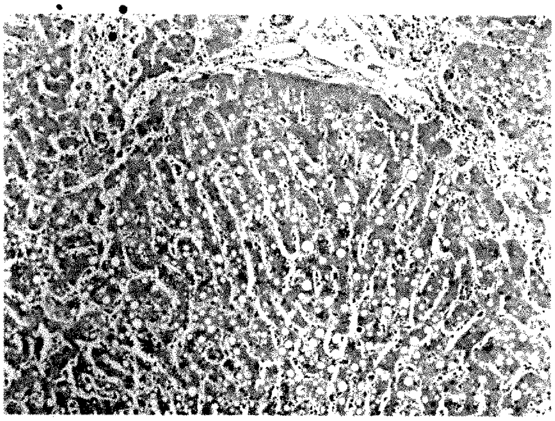

Fig. 2. Photomicrograph of regenerating liver at 24 hours after partial hepatectomy showing double cell plates. Note the larger hepatocytes in relation to portal tracts as compared with those in a more central site within the lobule. (× 60.)

rapidly during the early postoperative period. In one of our patients (*Case* 6) who came to operation 3 days after injury the weight of the right lobe of liver resected was 1045 g, and it was also noted that the left lobe of the liver was enlarged. This increase in size was accompanied by histological characteristics of regeneration, double cell plates (*Fig.* 2), and multiple mitotic figures (*Fig.* 3) being clearly visible at this early stage.

Metabolic changes frequently occur following removal of large quantities of liver tissue and are related to the process of liver regeneration.

Serum proteins: The serum albumin level began to fall within 24 hours of hepatic resection. Some recovery was noted between the second and fourth weeks and normal values were attained by the fifth to sixth postoperative weeks (*Table IX*).

Many clinicians recommend intravenous albumin supplements during this period (Pack et al., 1962; McDermott et al., 1963; Aronsen et al., 1969; Balasegaram, 1970), but in spite of intravenous albumin supplements of 75 g daily for 5 days in 2 cases (*Cases* 1 and 2) there was no improvement in the patients' serum albumin levels. We subsequently abandoned the practice of routine albumin supplements, with no adverse effects. The total serum protein levels were found to be low on the first postoperative day in all cases, but returned to normal levels within 2–3 weeks despite a persistently low serum albumin fraction. This could account for the lack of any clinical evidence of hypoproteinaemia (e.g. oedema).

Hypoglycaemia: Episodes of hypoglycaemia occurred in 5 of our 8 patients, and in a sixth (*Case* 7) an episode of collapse was treated successfully by the administration of 50 ml 50 per cent dextrose, although objective evidence of hypoglycaemia was not obtained. Blood sugar levels of less than 90 mg/100 ml were regularly recorded in these patients for up to 16 days after injury, but the reduced levels were slight and clinical signs of hypoglycaemia were not always evident. All these episodes occurred despite infusion of 5 per cent dextrose solution. Three of the episodes of hypoglycaemia occurring within the first 48 postoperative

hours were significant in that they produced sweating, tachycardia and collapse.

Jaundice: Jaundice occurred in all our patients and on occasions was a worrying clinical feature. Two patterns emerged from the study of our cases, one in the patients who survived and the other in those who died.

In the patients who survived the rise in serum bilirubin was not great. Indeed, it was no higher than 10 mg/100 ml and reached a peak within the first postoperative week, falling to normal levels by the end of the second week (except for one case in which it remained elevated for 4–5 weeks). In some of these patients the conjugated and unconjugated fractions of bilirubin were measured. It was found that elevation occurred in both fractions but the unconjugated bilirubin fraction showed the greatest rise (*Fig.* 4).

Of the patients who died, one (*Case* 5) died too soon after operation for any detailed biochemical or haematological analysis to be performed, and in one further patient (*Case* 1) the available results were incomplete. Nevertheless, 2 of the cases (*Cases* 1 and 6) had similar features. Both had suffered prolonged hypotensive periods following injury, both had severe postoperative sepsis and both developed renal failure. At necropsy both showed evidence of acute pancreatitis which was severe in *Case* 6. In both these patients the jaundice was severe and very high serum bilirubin levels were reached prior to death (*Fig.* 5). Early rises in serum alkaline phosphatase were noted in both patients at the end of the first week. In contrast to the cases which survived, the serum bilirubin in these cases was mainly of the conjugated variety.

Serum enzymes: Changes in the serum enzymes occurred after resection. A rise in the serum alkaline phosphatase levels occurred during the third and fourth weeks in 3 patients (*Cases* 2, 4 and 8; *Table X*). However, in the patients who died (*Cases* 1 and 6) the rise in serum alkaline phosphatase (*Table X*) occurred somewhat earlier than in the other patients. The serum glutamic pyruvate transminase (SGPT) rose immediately after operation in each instance and then usually fell to normal levels by the second week (*Table X*). Liberation of the enzyme from the damaged liver cells is a likely reason for such rises in the enzyme levels. It is noteworthy that in one patient with raised SGPT levels (*Case* 6), large areas of necrosis within the remaining liver tissue were found at necropsy. While it is known that an increase in the bile duct pressure may be a factor leading to a rise in SGPT (Braun et al., 1959) all cases had a T-tube *in situ* and we find it difficult to accept this as an aetiological factor in our patients.

Discussion

The postoperative problems encountered after hepatic resection for blunt injury to the liver are due in part to the metabolic and haematological changes that result from major hepatic resection. In addition, the effects of associated injuries and postoperative sepsis have an important bearing on the management of these patients. In particular, injuries to the chest may produce respiratory difficulty in the early postoperative period.

It is important to recognize that early signs of pulmonary insufficiency may be subtle and should be anticipated. The effects of chest injury, the presence of a thoraco-abdominal incision and incision of the diaphragm, depression of the respiratory centre as a result of head injury and possibly the result of embolization of hepatic tissue or fat embolism may all contribute to the respiratory problems. In particular it is worth emphasizing the serious combination of hypoxia and hypovolaemia which may occur in seriously injured patients (Sellors, 1961). The value of adequate blood transfusion, allowance for the effects of head injury and frequent monitoring of blood gases cannot be overstated. From the evidence in our series it would appear that most patients with injuries severe enough to necessitate hepatic lobectomy will need positive pressure ventilation and a significant proportion will require tracheostomy.

The evidence we present clearly indicates that a policy of antibiotic prophylaxis in blunt liver injury is potentially worse than ineffective. Infections are certainly not prevented by such practice nor is there any attenuation in the severity of infections when they do appear. Infections supervening on prophylaxis are always due to organisms resistant to the prophylactically administered antibiotics. We would suggest that management is best directed to the prompt diagnosis of significant infection by daily or more frequent bacteriological investigation and the intensive treatment of infection diagnosed clinically or in the laboratory. It is true that several of the metabolic and surgical complications of hepatectomy can mimic infection and the institution of treatment for infection on clinical diagnosis alone must remain a matter of delicate clinical judgement. It is, however, also true that inappropriate antibiotic therapy instituted on this basis is tantamount to prophylaxis which has its own hazards as already noted.

In general terms antibiotic policy should be to treat early infections as specifically as possible and to reserve broad spectrum therapy with such drugs as gentamicin, carbenicillin or the cephalosporins for the more complicated situations that may arise later.

The theoretical reasons for the bleeding disorders encountered after partial hepatectomy are well illustrated by our cases. Trauma to the liver is often associated with other major injuries. The liver itself is a friable vascular organ and even without haemostatic defect, profuse bleeding in these patients is not surprising. Indeed, 7 of the 8 cases in the present series required large transfusions. Stored blood is deficient in functional platelets and in labile coagulation factors V and VIII. Thrombocytopenia and coagulation factor deficiency may thus follow large transfusions of stored blood and it is possible this may even exert a positive thrombocytopenic effect (Stefanini, 1962; Ingram, 1965). In addition, the liver has important functions in maintaining normal haemostasis. It is the only site of synthesis of fibrinogen and the main site of synthesis of the vitamin-K-dependent clotting factors II, VII, IX and X and of factor V. By virtue of its reticulo-endothelial content it plays a part in clearing activated coagulation factors (Spaet et al., 1961). It also has a role in preventing excessive fibrinolysis, possibly by producing antiplasmin (Sherry, 1968). Impairment of liver function can thus result in coagulation defects and increased fibrinolysis. Depressed fibrinogen levels are a late result of severe hepatic impairment because of the relatively long half-life of circulating fibrinogen. The half-life of the activity of certain coagulation factors, e.g. factors V, VII and IX, however, is much shorter and with impaired synthesis deficiency readily occurs.

Finally, intravascular coagulation may accompany severe injuries or surgical procedures and may be aggravated by anoxia and hypovolaemia (Hardaway, 1966). Intravascular coagulation results in variable fibrinogen loss and thrombocytopenia with activation and then depletion of the labile coagulation factors V and VIII. Lysis of deposited fibrin results in increased levels of circulating fibrin degradation products and these may interfere with the polymerization of fibrin and prolong the thrombin clotting time. It should be noted, however, that FDP could conceivably be absorbed from haematomas, and raised levels alone should not be accepted as definite evidence of intravascular coagulation.

The complex nature of the coagulation defects makes specific therapy difficult and perhaps dangerous. Preparations of concentrated liver factors (factors II, VII, IX and X) are available but experience of their use is limited. The clotting factors which they contain may be more active than in their native form and their administration is best avoided if there is evidence of intravascular coagulation. The treatment of intravascular coagulation is also difficult. Theoretically, administration of heparin will arrest the condition but its early use in surgical cases is precluded. It may also be possible to treat other specific defects but therapy with concentrated coagulation factors may aggravate intravascular coagulation. Increased systemic fibrinolysis did not appear to be common after partial hepatectomy and fibrinolytic inhibitors were not used. These substances may also aggravate intravascular coagulation.

Because of the difficulties of specific therapy adequate blood replacement, particularly with fresh blood, is the mainstay of treatment. Fresh blood provides platelets and coagulation factors and is important for the prophylaxis of haemostatic defects. It is usually possible in this country to obtain fresh blood within a few hours from local donor sessions.

The low serum albumin levels recorded cannot be entirely explained on the basis of the loss of synthetic capacity of the liver as a result of tissue depletion, since the drop in serum albumin level was immediate and it has been shown that even complete cessation of albumin production only results in a 25 per cent decrease in serum level after 8 days (Martin and Neuberger, 1957). In addition, increased capillary permeability, with indirect loss of plasma proteins into the extravascular spaces, has been demonstrated in dogs after total hepatectomy, and may account for some of the postoperative fall in serum albumin levels that we have observed. Of the other factors which might account for the changes observed, the effects of infusion of large volumes of fluid, exudation from the embolization of hepatic tissue or fat embolism may all contribute to the respiratory problems. In particular it is worth emphasizing the serious combination of hypoxia and hypovolaemia which may occur in seriously injured patients (Sellors, 1961). The value of adequate blood transfusion, allowance for the effects of head injury and frequent monitoring of blood gases cannot be overstated. From the evidence in our series it would appear that most patients with injuries severe enough to necessitate hepatic lobectomy will need positive pressure ventilation and a significant proportion will require tracheostomy.

raw surface of the liver after operation and postoperative sepsis may be important.

Some surgeons have reported no significant change in the blood sugar level of their patients (Pack and Molander, 1960; Lin and Chen, 1965). However, we have found that hypoglycaemia can be significant following partial hepatectomy, and others (McDermott et al., 1963) have reported similar experience. Hypoglycaemia should be expected since in the fasting state blood glucose is derived directly from liver glycogen and this is seriously depleted following liver resection. Furthermore, enzyme activities related to liver glycolysis are depressed during the initial post-injury period (Weber and Cantero, 1955; Van Lancker and Sempoux, 1958).

Jaundice occurred in all our patients in the postoperative period and two patterns emerged from the study of our cases. In the patients who survived the serum bilirubin level never rose above 10 mg/100 ml and reached a peak within the first postoperative week (type I). In these cases both the conjugated and unconjugated fractions of bilirubin were elevated but the unconjugated bilirubin fractions showed the greatest rise. Haemolysis of transfused red blood cells and absorption of haematoma with increased production of bilirubin are possible causes of this rise in unconjugated bilirubin. Furthermore, minor elevations in the conjugated fractions of bilirubin may be seen in haemolytic states (Schmid, 1972). In addition to these factors, impaired hepatic uptake and defective excretion of bilirubin are known to occur after partial hepatectomy in animals (Weinbren and Billing, 1958; Wood et al., 1973). There is, however, good evidence that liver enzyme activities show only a transient decrease following partial hepatectomy (Bengmark, 1970), and the gradual fall in the plasma unconjugated bilirubin in our patients testifies to cellular recovery. There must, however, be some element of obstruction of bile outflow since bilirubinurea was detected in all our cases. T-tube cholangiography did not demonstrate any block in the extrahepatic part of the biliary ductal system so that the obstructive element must be intrahepatic in origin. This factor was of much greater importance in the severely jaundiced patients (type II) with serum bilirubin levels above 10 mg/100 ml.

In these severely jaundiced patients (type II) haemolysis could not account for the progressive rise in bilirubin levels. It has been well documented that prolonged intrahepatic cholestasis may give rise to great increases in conjugated bilirubin levels with only variable changes in the level of the serum transaminase and alkaline phosphatase (Sheldon and Sherlock, 1957). The findings in our patients are typical of severe cholestasis, and indeed histological examination of the liver remnant at post-mortem confirmed this. In addition, it should be noted that these patients not only suffered preoperative and intra-operative hypotension but were severely infected after operation, and it is known that sepsis is a cause of intrahepatic cholestasis (Fahrländer et al., 1964). Some have suggested that severe reduction in the liver cell mass may lead to engorgement, increased intrahepatic pressure and consequent pressure on small intrahepatic biliary radicals (McDermott, 1970). Others (Almersjö et al., 1969) have proposed that the postoperative jaundice may be due to increased pressure within the bile ducts. We find this difficult to accept since the presence of T-tube drainage did not prevent the development of jaundice in our patients. Bile pigment precipitation with intrahepatic cholestasis would seem to be a much more likely cause of the jaundice, and indeed some degree of postoperative cholestasis may occur in any patient who has undergone a major operation (Schmid et al., 1965). Finally, it should be noted that the presence of acute renal failure might contribute to the retention of conjugated serum bilirubin, since it has been shown that jaundiced patients with impaired renal function cannot secrete conjugated bilirubin efficiently (Wallace and Owen, 1964). Lucas et al. (1969) have shown an increased morbidity and late mortality rate with extrahepatic biliary drainage in patients with liver injury. These studies include patients with injury of varying severity and a preponderance of patients with penetrating liver wounds. The evidence against the use of T-tube drainage in major blunt injury to the liver is as yet inconclusive and we continue to advocate T-tube drainage of the common bile duct after liver resection for injury. This allows the early detection of haemobilia and regular bacteriological culture of bile and, in addition, T-tube cholangiography (*Fig.* 6) can exclude an extrahepatic obstruction in the jaundiced patient after liver resection. Jaundice alone is not an indication for reoperation, particularly if the serum proteins and other parameters of liver function are showing signs of recovery.

The remarkable regenerative capacity of the liver following major hepatic resection is well documented. It has recently been shown, using post-mortem observations, weight estimations and serial radioisotopic liver scans taken from some of the patients reported here, that liver regeneration in man commences soon after operation and progresses rapidly during the subsequent 2–3 weeks, there being little increase in the liver size thereafter (Blumgart et al., 1971).

The speed of this regenerative activity has a bearing on the metabolic activity. During regeneration much of the cellular energy is occupied with division and less is available for normal liver function. We have shown in this series of patients that liver cellular function is recovering within 2 weeks of major hepatic resection and by the sixth postoperative week is virtually normal. It should not be forgotten that many of the reports relating to the metabolic changes after liver resection are concerned with changes observed after resection for tumour. In such patients, and especially if they have large tumours, the residual healthy tissue may already have undergone some degree of compensatory hyperplasia and hypertrophy. Removal of such a tumour may produce only relatively small changes in the functional capacity of the residual liver. No such compensatory changes could have taken place before resection for injury. The striking relationship between the speed of regeneration and the consequent metabolic recovery is a factor to take into account in clinical management. In particular, we have found that routine administration of albumin in the postoperative period has not been necessary in our patients, and have noted the recovery of serum albumin levels coincident with return in function of the remaining liver.

The effects of hypoperfusion as a result of shock should not be underestimated. In particular, a rising fraction of conjugated serum bilirubin (in the presence of a patent extrahepatic biliary tree), an early rise in the alkaline phosphatase, a sustained rise in the SGPT or a continuing fall in serum protein levels after the second week should be taken as indicative of a severe degree of liver damage.

The application of the ^{99}Tc^{m} phosphate bone scan to the study of breast cancer

D. L. CITRIN, R. G. BESSENT, W. R. GREIG, N. J. McKELLAR, C. FURNIVAL AND L. H. BLUMGART*

SUMMARY

Comparison of the gamma camera bone scan and radiological survey in 190 patients with breast cancer has confirmed the superiority of the bone scan in the positive diagnosis of skeletal metastases. In 47 patients with known (X-ray positive) bony metastases the scan was positive in all but 2, and in 24 (50 per cent) the scan showed more lesions than the X-ray had indicated. In 60 patients with a clinical suspicion of bone metastases but negative X-rays, the scan was positive in 29 (48 per cent). Eighty-three patients with primary breast cancer were studied at the time of initial presentation. All had a normal radiographic skeletal survey but 24 (27 per cent) had scan evidence of occult metastases. It is concluded that a bone scan is indicated in all patients with breast cancer where skeletal metastases are suspected.

Repeated bone scans may introduce new therapeutic possibilities, by providing an earlier objective index of progression of metastatic disease and also by providing a quantitative method of assessing the response to therapy.

BONE scanning is a valuable diagnostic aid in the detection of skeletal metastases (Charkes et al., 1968) and has shown great promise in the study of breast cancer (Galasko et al., 1968). Because of the recent introduction of the ^{99}Tc^{m} phosphates, high quality bone scans are now available in all hospitals with scanning facilities (Citrin, Greig et al., 1974). In this paper we record our experience of the ^{99}Tc^{m} bone scan and radiographic skeletal survey in 190 patients with breast cancer.

Materials and methods

One hundred and ninety female patients with breast cancer and 70 control subjects were studied. The breast cancer patients may be divided into three main groups:

1. Patients with known bony metastases (X-ray positive) who were scanned to allow us to develop and validate our technique (47 patients).
2. Patients in whom there was a clinical suspicion of metastases but no definite lesion seen on X-rays (60 patients).
3. Patients scanned at the time of initial presentation and primary treatment (83 patients).

Each patient was scanned 4 hours after the intravenous injection of 10 mCi of ^{99}Tc^{m} phosphate, using a Nuclear Enterprises Scinticamera IV gamma camera. All the scans were recorded on Polaroid film. Multiple overlapping views of the skeleton were obtained with the patient either seated or standing (for pelvic views). Twelve views were obtained: right and left lateral skull (2 views), cervical, dorsal and lumbar spine (3 views), right and left shoulders, and proximal humeri (2 views), sternum and anterior ribs (1 view), right and left anterior and posterior pelvis with proximal femora (4 views). Spinal pictures were taken with 300 000 counts and all other pictures with 200 000. In some patients a more limited examination (restricted to known tumour-bearing areas) was made.

Table I: RESULTS OF SCAN AND X-RAY IN PATIENTS WITH KNOWN BONY METASTASES

	Total no.	Scan positive	Scan negative	Scan suspicious
X-ray positive	47	45	2	0
X-ray negative	0	0	0	0
X-ray suspicious	0	0	0	0
Total	47	45	2	0

Table II: RESULTS OF SCAN AND X-RAY IN PATIENTS WITH CLINICAL SUSPICION BUT NO DEFINITE METASTASES ON X-RAY

	Total no.	Scan positive	Scan negative	Scan suspicious
X-ray positive	0	0	0	0
X-ray negative	59	28	26	5
X-ray suspicious	1	1	0	0
Total	60	29	26	5

Table III: RESULTS OF SCAN AND X-RAY IN PATIENTS WITH PRIMARY BREAST CANCER

	Total no.	Scan positive	Scan negative	Scan suspicious
X-ray positive	0	0	0	0
X-ray negative	81	21	49	11
X-ray suspicious	2	1	1	0
Total	83	22	50	11

In all the patients a radiological skeletal survey was obtained within 1 week of the scan, comprising anteroposterior and lateral views of the skull, anteroposterior and lateral views of the cervical, dorsal and lumbar spine, chest with rib views and pelvis. The scans and X-rays were independently read by a nuclear medicine physician and a consultant radiologist respectively. Results were recorded as positive, negative or suspicious for metastases. The results of the two investigations were then compared.

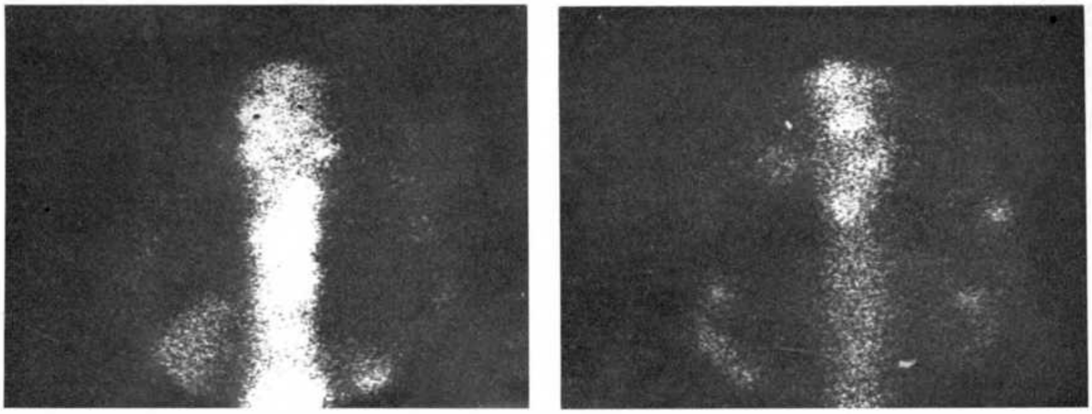

Fig. 1. Case with X-ray-positive metastases in T10 and T11; remainder of X-ray skeletal survey negative. *a*. Scan of dorsolumbar spine shows lesions throughout the lower dorsal spine. *b*. Anterior ribs and sternum are extensively involved.

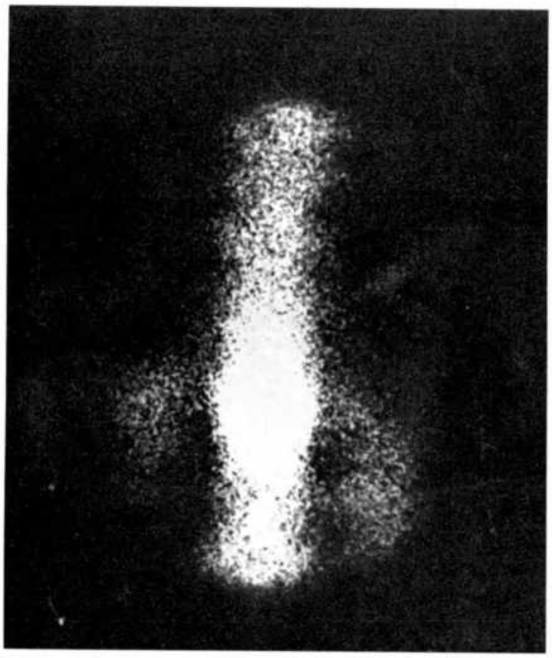

Fig. 2. Scan of a 44-year-old patient who had undergone mastectomy 2 years before. She presented with back pain, but an X-ray was negative. A lesion was seen in the lower dorsal spine on a scan. One week's radiotherapy relieved the pain.

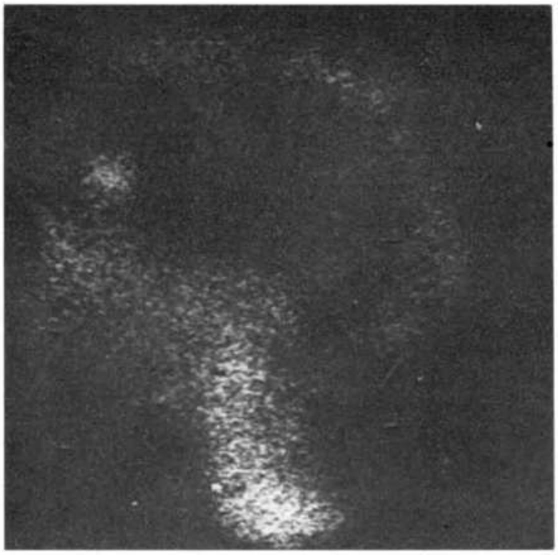

Fig. 3. Scan of a 50-year-old patient with cancer of the left breast (clinically stage II) at the time of presentation. X-rays taken at this time were negative. The scan shows tumour of the left frontal bone, which was confirmed radiologically 6 months later.

Seventy control subjects were scanned using an identical technique to that employed in the breast cancer patients. The controls were postmenopausal females and male patients over the age of 35 with no history or evidence of malignant disease. The control scans were reported without knowledge of the clinical history.

Results

The results are summarized in *Tables I–III*. In all but 2 of the 47 patients with radiographically demonstrable bony metastases the scan showed corresponding abnormalities (*Table I*). In 24 (50 per cent) the scan clearly showed metastases to be more widespread than the X-ray had suggested (*Fig*. 1). The two X-ray-positive scan-negative cases are of interest in that both had had spinal metastases for over 5 years. X-rays showed healed sclerotic lesions, and we have interpreted the negative scans as indicating inactive disease.

In 60 patients, despite the clinical suspicion of metastatic disease, the X-rays were not confirmatory (*Table II*). Twenty-nine of these patients (48 per cent) had positive bone scans, and in many of these cases the presence of metastatic tumour has been confirmed by the clinical course or subsequent studies (*Fig*. 2). Five patients had areas on the scan which were considered suspicious but not diagnostic of metastases, and follow-up studies are being carried out. The remaining 26 patients had normal bone scans.

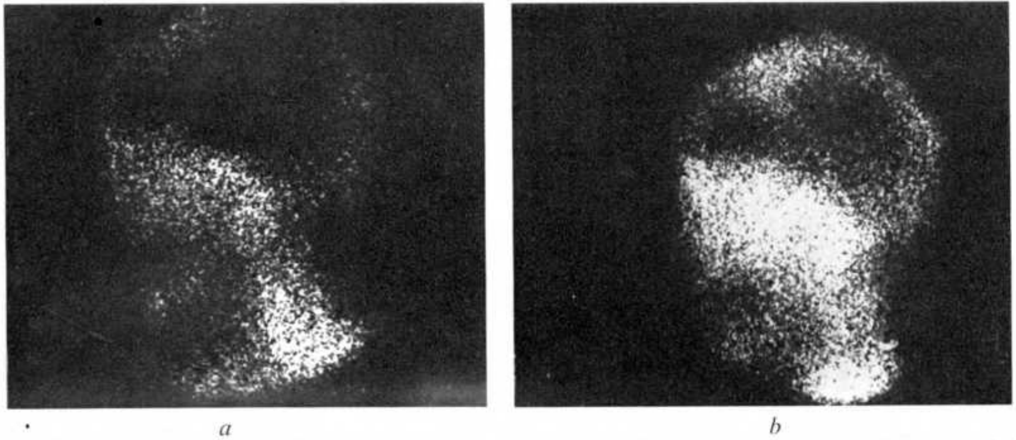

Fig. 4. Scans of a 62-year-old patient with stage I breast cancer (*a*) at the time of mastectomy and (*b*) 6 months later, when the patient was clinically well. Both scans show a lesion of the left frontoparietal bone which has progressed. X-rays were consistently negative on both occasions.

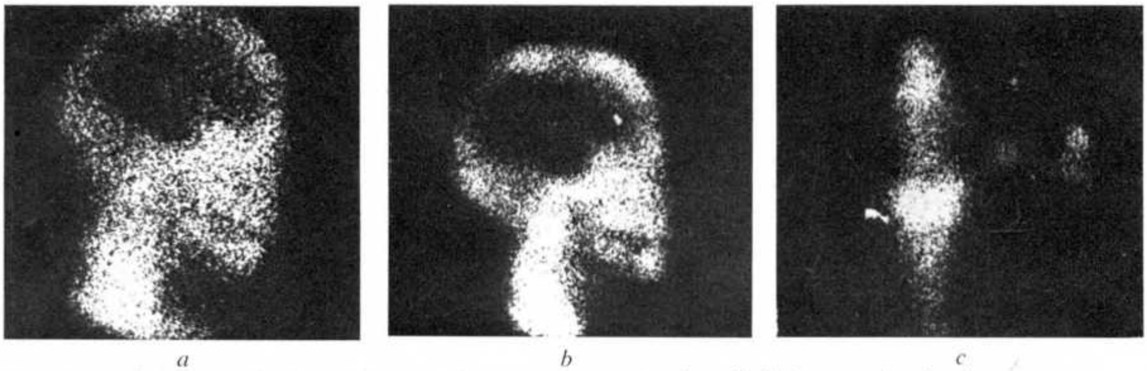

Fig. 5. Scans of a 49-year-old patient with stage II breast cancer (*a*) at the time of initial presentation showing metastases of the skull, and (*b*) and (*c*) 6 months later, when the patient was clinically well and radiologically negative. There are lesions in the skull and left clavicle (tumour in clavicle was scan negative at the time of presentation).

Eighty-three patients with primary breast cancer were scanned and X-rayed as part of their initial assessment (*Table III*). None of these patients had definite metastases visible on the radiographic skeletal survey. Twenty-two (27 per cent) were considered to have changes on the scan diagnostic of metastatic deposits, and in a further 11 cases (14 per cent) there were changes suspicious but not entirely diagnostic of metastases. In 4 patients to date X-rays have confirmed the presence of metastatic tumour at sites initially indicated by the bone scan (*Fig*. 3). In 11 patients serial scans have documented consistent abnormalities which in several patients have clearly progressed (*Figs*. 4, 5).

In 2 control subjects, abnormalities were noted which could be interpreted as metastatic deposits. In one subject the X-ray was normal and in the other the X-ray demonstrated a localized concentration of bone in the area indicated by the scan. Both control subjects remain well 1 year after scanning.

Discussion

Our preliminary results (Citrin, Greig et al., 1974) and those presented here have led us to conclude that the ^{99}Tc^{m} phosphate scan allows earlier and more accurate diagnosis of skeletal metastases than the conventional X-ray. In all the patients with X-ray-positive metastases (with the exception of 2 with probably inactive lesions) scanning confirmed the presence of metastases and in 24 (50 per cent) showed additional lesions not yet visible on the X-ray. Forty-eight per cent of patients with a clinical suspicion of metastases and 27 per cent of primary breast cancer patients were also shown by scanning to have metastases not demonstrable in the radiographic skeletal survey. The incidence of 'false positives' in the control group was acceptably low (3 per cent).

The scan is well tolerated by the patient; she does not need to undress and there is less physical manipulation than with conventional radiography. We have recently increased the isotope activity given; we now routinely give 15 mCi of ^{99}Tc^{m}-labelled ethane hydroxydiphosphonate (EHDP), which appears to be the best of the available compounds (Citrin et al., 1975). Scanning time is no longer than 30 minutes in any one patient and high quality bone scans are consistently obtained.

The technique of bone scanning is particularly appropriate to breast cancer because 85 per cent of patients who die from this disease have bone metastases (Jaffe, 1958). Against this background a detailed study of patients with primary breast cancer is currently in progress at Glasgow Royal Infirmary. Patients are scanned before commencing treatment and at 6-monthly intervals thereafter. The final results of this study will be published at a future date. Of interest at the present time is the finding that the incidence of X-ray-negative patients with positive scans in our group was 27 per cent, which is similar to that previously reported by Galasko et al. (1968). Clearly, the bone scan may provide valuable clinical information in the initial assessment of the primary case. The use of this information in relation to management of the individual case and the formation of valid groups for future clinical trials is being assessed.

Since EHDP is convenient, non-toxic and imposes only a small radiation burden (Citrin et al., 1975), serial scanning is now feasible. Scans repeated at intervals have demonstrated progressive metastases in several patients who were previously scan-negative and who remain entirely symptom-free following mastectomy, and it appears that there is emerging a group of patients in whom these lesions can now be identified as they occur by using serial scans. In this group the possibility of treating these demonstrable lesions at an early stage (even before symptoms develop) must now be considered. The conclusion that chemotherapeutic and hormonal methods are capable of inducing only a temporary remission of bone metastases is drawn from experience of metastases demonstrable by radiographic methods, and it seems unwarranted to conclude at the present time that the same result would necessarily be found in the treatment of early lesions, demonstrated by scanning but not yet visible on the X-ray. It is possible that asymptomatic metastases could be eradicated by commencing treatment at this early stage.

It has previously been suggested that the bone scan may provide a method of assessing response to therapy (Galasko and Doyle, 1972). For this purpose we have developed a rapid inexpensive method of quantifying tumour activity using the bone scan. The technique of quantitative bone scanning offers great promise as a research tool by providing an accurate method of assessing the effects of therapy on metastases which may be asymptomatic and radiologically invisible (Citrin, Bessent et al., 1974).

Our studies over the past 18 months suggest that this area may well represent the most important therapeutic application of bone scanning in breast cancer.

Cystic thyroid nodules

MICHAEL K. G. MA AND G. B. ONG*

SUMMARY

Among 300 patients with thyroid nodules subjected to a needle drill biopsy, 62 were found to contain cystic lesions. Analysis of these 62 cases showed that in 17 the swelling had completely disappeared after the biopsy. The remaining 45 had residual or recurrent swellings. Operative treatment was carried out in 35, which consisted of 28 (80 per cent) nodular goitres, 6 (17·1 per cent) adenomas and 1 (2·9 per cent) carcinoma.

ABOUT 15 per cent of all thyroid nodules are cystic (Crile, 1966). The contents may vary from thick brownish colloid material to thin pale fluid. Clinically they present as solitary nodules either of recent onset and rapid growth or with a history of long duration with little fluctuation in size. Regardless of the mode of development, these cystic nodules are usually medium-sized with a diameter of about 2–5 cm and hard in consistency. They invariably show poor uptake of radioactive I_2 in the thyroid scan. Hence they stay high on the list for operative treatment because of the risk of malignancy. However, when the nodules are excised the majority of them turn out to be benign lesions. There is a paucity of reports in the literature on the incidence of carcinoma in cystic thyroid nodules. Preoperative needle biopsy is still a controversial practice and performed only in a selected group of patients. We set out to study the usefulness of such a procedure in the management of thyroid cyst and in obtaining early histological diagnosis.

Materials and methods

In the past 3½ years 300 drill biopsies of the thyroid gland have been performed in the Surgical Thyroid Clinic, University of Hong Kong. Patients selected for study included those presenting with either a solitary nodule or a multinodular swelling with poor radioactive iodine uptake in the scan. A high speed pneumatic drill was used. It has a needle of 1·5 mm internal diameter and is driven by compressed air at 5 kg/cm². Under local anaesthesia a small skin incision was made and the needle was inserted into the centre of the nodule. After it had penetrated the thyroid capsule, it was disconnected from the machine and withdrawn with mild suction. Whenever fluid was aspirated an attempt was always made to empty all the contents by gentle pressure on the gland. The fluid was measured and sent for cytological study. The incision was then covered with an Elastoplast dressing and the patient was discharged.

Of the 300 patients studied, 62 were found to have cystic lesions containing fluid of various character and quantity. There was thin yellowish fluid in 10, dark brownish fluid in 34 and thick colloid material in 18 (*Table I*). The amount ranged from 1 to 60 ml with an average of 8 ml.

These 62 patients were followed up regularly in the Thyroid Clinic. In 17 (27·4 per cent) the swelling completely disappeared and no further surgical intervention was indicated. However, they were all examined on a monthly basis in case of further development. Thirty-five (56·5 per cent) of the 62 patients were subsequently operated upon because of recurrent or residual swelling. Of these, 28 (80 per cent) were nodular goitres, 6 (17·1 per cent) were adenomas and only 1 carcinoma (*Table II*). The remaining 10 patients had some residual swelling in the neck but they refused operative treatment. However, they have been followed up for periods of 2 months to 3½ years and are all in good health with no signs of malignancy.

Table I: TYPE OF FLUID ASPIRATED IN 62 PATIENTS

Type	No. of cases
Thin yellow fluid	10
Thick colloid material	18
Dark brownish fluid	34

Table II: RESULTS OF DRILL BIOPSY IN 62 PATIENTS

Result	No. of cases
Nodule subsided	17
Residual swelling with no operation	10
Residual or recurrent swelling with operation	35
Nodular goitre	28 (80%)
Adenoma	6 (17·1%)
Papillary carcinoma	1 (2·9%)

Discussion

Needle biopsy of the thyroid gland has long been a controversial practice. It is only occasionally performed in apparently benign lesions because of the potential risk of tumour dissemination. Since the introduction of the high speed pneumatic drill, Deeley and Pollock (1966) have successfully used it to biopsy enlarged lymph nodes, lung, thyroid, breast and various soft tissue tumours. Risk of cancer dissemination was shown by Burn et al. (1968) to be low. We have therefore used the drill to biopsy 300 patients with thyroid swellings. Patients selected for the study included those presenting with a solitary nodule, a multi-nodular swelling with a 'cold' area in the thyroid scan or non-toxic diffuse swellings. One of the aims of this study was to evaluate the management of a cystic thyroid nodule by aspiration. If such cysts can be treated by simply emptying the contents without risk of leaving behind a carcinoma, then a large number of unnecessary operations can be avoided.

---

* Department of Surgery, University of Hong Kong, Queen Mary Hospital, Hong Kong.

Sixty-two patients in this series were found to have cystic thyroid nodules. The cysts contained fluid of various quality and quantity which was aspirated by a high speed pneumatic drill. The character of the fluid had no significant bearing on the nature of the lesion. In 17 the swelling completely subsided with no recurrence. We chose to postpone operative treatment of these patients and to follow them up at monthly intervals. In 10 there were some residual swelling or recurrence after the drill biopsy but the patients refused operation. Both groups of patients have now been followed up for periods of 2 months to 3½ years. So far none of them has shown any signs that warrant an early exploration. In the remaining 35 of the 62 patients operation was carried out, the indication being residual or recurrent swelling. Of these, 28 (80 per cent) had nodular goitre, 6 (17·1 per cent) had adenoma and only 1 patient (2·9 per cent) had a papillary carcinoma. If we assume the cystic lesions that disappeared after aspiration to be benign, then the incidence of carcinoma in cystic thyroid nodules was 1·9 per cent. Crile (1966) treated 58 cases of thyroid cysts with needle aspiration and encountered no malignant tumour. It would appear that such cystic lesions of the thyroid gland, whether solitary or multinodular, and which routinely show poor uptake of radioactive iodine in the scan, could well be safely managed by this simple method. A preoperative drill biopsy would serve as both a diagnostic and therapeutic procedure. It is safe and was well tolerated by our 62 patients without any complication. Also, if a careful cytological examination were done on every sample of cyst contents, there should be no difficulty in diagnosing the small proportion of cases which truly warrant an operation.

Thyroid cancer: twenty years' experience in a general hospital

D. J. CAMPBELL AND R. H. SAGE*

SUMMARY

Twenty years' experience of thyroid cancer in a district general hospital has been reviewed. Its incidence, prognosis and natural history have been studied. Particular attention has been focused on the relationship of malignant to benign goitre. The relevance of this to the treatment of 'apparently benign goitre' is discussed.

Clinical evidence is presented supporting the hypothesis that differentiated thyroid carcinoma evolves from a solitary focus through a multinodular form before presenting the picture of a frankly malignant locally invasive cancer.

An increase in the incidence of papillary carcinoma is confirmed.

CANCER of the thyroid is a rare disease which in the Birmingham region has an incidence of 2·0 females to 0·6 males per 100 000 of the population (*Table I*). It constitutes only 0·7 per cent of all cancers in the female and 0·2 per cent in the male (Waterhouse, 1974). In view of this, it is not surprising that the majority of series reporting thyroid cancer originate from either regional cancer centres or individuals renowned as thyroid surgeons. The selection applied to these series favours carcinoma (Crile and Dempsey, 1949) and consequently they do not reflect the experience of general surgeons nationally.

Table I: INCIDENCE OF THYROID CANCER BY AGE IN THE BIRMINGHAM REGION DURING 1960–5

Age	M	F	Age	M	F	Age	M	F
0–4	0·0	0·0	35–39	0·3	1·4	70–74	2·8	6·0

Total	54

The identification of a malignant goitre amidst numerous benign or apparently benign goitres has always been a problem facing general surgeons. Whilst some cancers are readily diagnosed, others present in the guise of benign goitres. This latter group requires further elucidation as the literature abounds with conflicting evidence concerning the cancer risk in apparently benign goitres. This is the result of a wide variation in case selection and depends on whether patient sampling occurs in goitrous or non-goitrous areas (Wilson, 1973).

The present study is based on the experience of thyroid cancer in a district general hospital during the period 1953–73. Attention has been focused primarily on the incidence of thyroid cancer in surgical practice. Its relationship to benign goitre, particularly the solitary nodule and non-toxic goitre, has been clarified. In addition, the natural history of thyroid cancer has been considered with particular reference to its response to treatment. It is felt that in this unselected group of patients is mirrored the experience of the vast majority of general surgeons. The Birmingham region does not include any areas of endemic goitre.

Clinical material

Fifty-four primary thyroid malignancies have been reviewed. These were diagnosed and treated at Selly Oak Hospital, Birmingham, between 1953 and 1973 and have been under constant supervision following initial diagnosis. All patients subjected to thyroidectomy during this same period have been similarly studied.

In every case the initial histological diagnosis has been verified by re-examination of the original slides. 'Representative sections' have been employed in both surgical and post-mortem studies. No 'whole organ' sections were prepared. The histological classification employed is based on the terminology of Meissner and Warren (1969).

Where appropriate, figures relating to thyroid cancer in the entire Birmingham region have been obtained from the Regional Cancer Registry.

Incidence

During the period 1953–73, 1058 thyroidectomies were performed at Selly Oak Hospital. In 45 of these cases a diagnosis of primary carcinoma was confirmed; an overall operative incidence of 4·25 per cent. Nine primary carcinomas, not treated surgically, were verified at post-mortem, having been undiagnosed clinically or considered inoperable. Three secondary thyroid carcinomas were encountered during the same period. Classification of primary growths by histological type is shown in *Table II*. *Fig.* 1 shows the overall age distribution at presentation.

---

* Selly Oak Hospital, Birmingham.

A consideration of the carcinomas in females shows a marked difference in the age distribution of differentiated and anaplastic growths (*Fig.* 2). Differentiated carcinomas first appear during the teens (postpubertal rise) to reach a peak between the ages of 45–55 years (menopause). There is then a gradual decline in the postmenopausal period. In contrast, anaplastic tumours exhibit a markedly increased incidence in the perimenopausal period, reaching a peak at 70 years. A similar but less marked age differential is recorded in the male.

The aetiological significance of these findings is unclear. Thyroid-stimulating hormone is known to be important in the development of differentiated thyroid carcinomas (Taylor, 1969a) and may be responsible for this distinctive age distribution. The accurate determination of physiological variations in the concentration of thyroid-stimulating hormone is not possible with present assay techniques (Jacobs and Lawton, 1974). The aetiology of thyroid carcinoma will become clearer when improved techniques allow an assessment of the effect of puberty and the menopause on the output of thyroid-stimulating hormone.

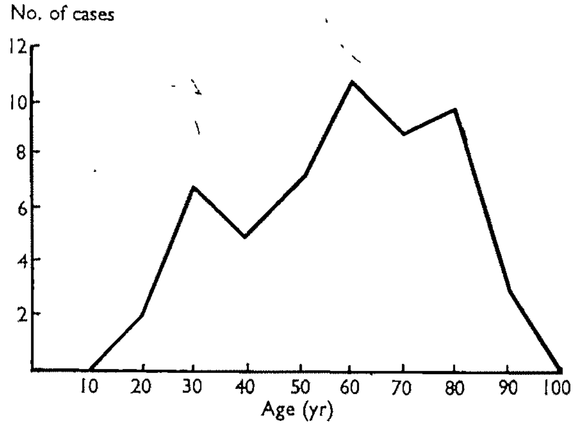

Fig. 1. Distribution by age of all thyroid cancers presenting at Selly Oak Hospital during the period 1953–73.

Increase in the incidence of papillary carcinoma

An increase in incidence of papillary carcinoma has been observed. This is most marked in the male, but a gradual rise has also been observed in the female. The percentage distribution of papillary carcinoma for 3-year periods during 1960–71 is recorded in *Table III*. The figures shown are those for the Birmingham region as they give a clearer indication of the trend than those obtained purely for Selly Oak Hospital. They confirm previous reports in the American literature (Beahrs et al., 1951; Crile, 1971). Papillary carcinoma is known to be associated with increased intake of iodine (Doniach, 1969). In the British Isles iodized table salt accounts for only 1·5–2·0 per cent of the total salt market. This, nevertheless, represents a sixfold increase when compared with the level of 1930 (Wenlock, 1974).

Diagnosis at presentation

In 21 patients (38·9 per cent) a correct diagnosis was possible on clinical grounds alone. These were invariably rapidly progressive anaplastic tumours, which did not present diagnostic problems. Nineteen of these patients have since died of their disease.

The remaining 33 carcinomas (61·1 per cent), viewed with varying degrees of clinical suspicion, were categorized as shown in *Table IV*. These categories afford clinical camouflage and it is therefore important to know the percentage of each group that is likely to be malignant. In this way an appropriate degree of clinical suspicion can be brought to bear in individual

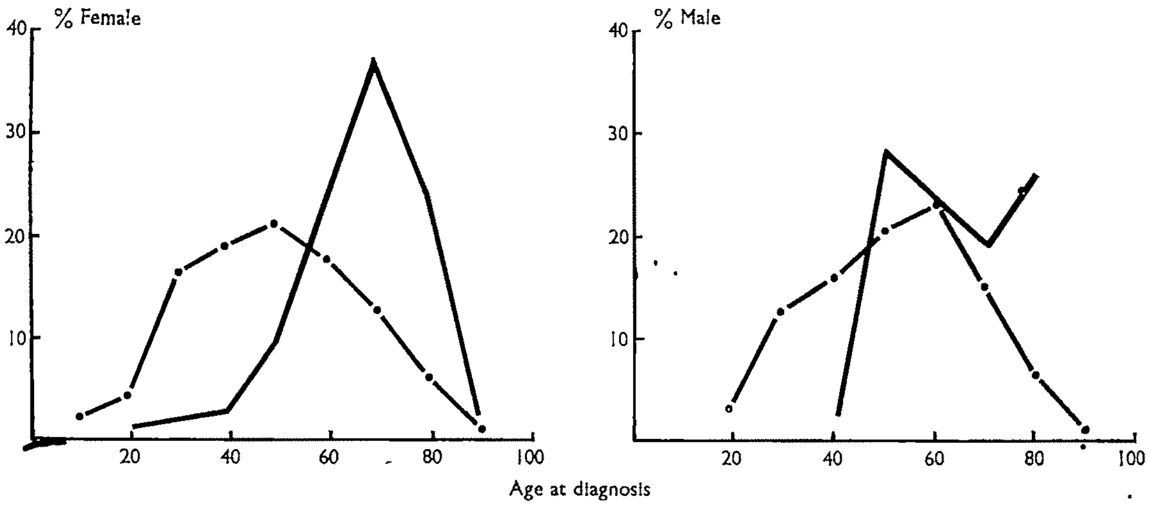

Fig. 2. Distribution by age (%) and sex of differentiated (· — ·) and undifferentiated (——) thyroid cancers in the Birmingham region.

cases. The percentages given in *Table V* are for those carcinomas that were not diagnosed clinically.

It is felt that the degree of selection applied to these goitres is neither more nor less than that applied in any other general surgical unit. Consequently, although these figures do not represent the incidence of carcinoma in toxic and non-toxic goitre amongst the general population they are figures having an important significance in surgical practice.

Solitary nodules

Eight of the clinically undiagnosed carcinomas presented in the form of a solitary nodule. They had been present for an average of 23 months (range, 1 month to 5 years) and were most common in the female (F : M ratio, 5 : 3). They presented at all ages, but most frequently in the 30–40 age group (average, 43 years). Two hundred and ninety-eight clinically solitary nodules were excised during the same period, giving a carcinoma incidence amongst excised solitary nodules of 2·7 per cent. Six nodules were well differentiated carcinomas, the remaining 2 being medullary (*Table VI*). Two of the well-differentiated growths showed evidence of early local invasion.

All solitary nodule carcinomas responded remarkably well to treatment. This involved subtotal resection of the affected lobe and, in one instance, resection of the isthmus. Two patients with evidence of local spread were additionally treated with suppressive doses of thyroxine, one of them also receiving local external irradiation. All these patients are alive, with no evidence of local or disseminated recurrence (*Table VII*). Average follow-up is 5 years 9 months, with a range of 1–15 years.

Multinodular goitre

Eighteen of the undiagnosed carcinomas presented as non-toxic multinodular goitres. They were selected for surgery on the usual clinical grounds. During the same period 141 non-toxic multinodular goitres were excised, giving a carcinoma incidence of 12·8 per cent. When all excised non-toxic goitres are considered together this figure becomes diluted to 8·7 per cent.

In contrast to solitary nodules the majority of these goitres had been present for many years, with an average of 6 years and 8 months. They therefore present later in life, the average age at presentation being 55, and predominantly in females (F : M ratio, 8 : 1).

These patients do consistently worse than those with solitary nodules. Six died of disseminated carcinoma, with a longest survival time of 6 years. Four patients are still receiving treatment for metastatic disease.

In 6 patients carcinoma supervened on a long-standing goitre (more than 10 years). As a group, these responded badly to treatment. Three died of disseminated disease, while 2 others have developed both local and distant metastases.

Toxic goitre

Three toxic goitres were found to contain carcinoma. Two of these were removed surgically, while the third

Female	42	57	52
Male	12	25	20

was discovered at post-mortem, the patient having died of thyrotoxic heart disease. Two were papillary, and the other a mixed follicular-papillary type.

The carcinoma incidence of 0·4 per cent in excised goitres is similar to the 0·354 per cent of Hurxthal and Heinemann (1958). Olen and Klinck (1966) reported an incidence of 2·5 per cent amongst hyperthyroid glands.

Results of treatment

The effect of age and sex on survival

Results of treatment for thyroid carcinoma in the female are significantly better than those obtained in the male. Female 10-year survival figures are better than those achieved at 5 years in the male (*Table VIII*). The age at presentation also exerts a marked influence on survival, as shown in *Table IX*. Patients with carcinoma presenting after 60 fare significantly worse than those with carcinoma occurring earlier. This applies equally to both sexes. It would appear, however, that females are selectively protected until they reach the postmenopausal period (*Table X*). Their good prognosis before this is responsible for the good overall survival figures for carcinoma presenting at an early age.

The effect of histological type of survival

The biological individuality of the various histological types of thyroid carcinoma has been confirmed by both pathological and epidemiological studies (Cuello et al., 1969). The difference in morbidity and mortality amongst the patients treated in the present series verifies this (*Table XI*).

Table IX: COMBINED MALE AND FEMALE SURVIVAL FIGURES BY AGE FOR ALL THYROID CANCER

Age at presentation	No. of cases	5-Year survival(%)	10-Year survival (%)
<30	4	100	100
30–60	22	75	64

Table XI: RESULTS OF TREATMENT IN FOUR HISTOLOGICAL TYPES OF PRIMARY THYROID CANCER

Type of cancer	No. treated	Tumour deaths	Non-tumour deaths	Alive with recurrence	Recurrence-free
Papillary	8	1	0	1	6
Follicular	10	3	1	2	4
Mixed papillary-follicular	5	0	0	1	4
Anaplastic	13	11	0	2	0

Papillary: Eight patients received treatment for papillary carcinoma. Two untreated carcinomas were discovered incidentally in patients dying of unrelated conditions. Amongst the treated group (*Table XII*), only one 'tumour death' has been recorded during the period 1953–73. This appears to have resulted from both extensive local infiltration at presentation and inadequacies in the treatment prescribed. Primary treatment, following confirmatory lymph node biopsy, was achieved with external irradiation alone. Thyroxine was not introduced until 10 months later following the development of systemic metastases. Thyroidectomy was not performed. Only one other patient has shown evidence of spread from papillary carcinoma. In this patient local infiltration made total excision impossible. She has therefore been treated with radioactive iodine.

In the remaining patients, tumours were confirmed within the thyroid capsule. Unilateral or bilateral resections were performed in response to operative findings. In no case was thyroid resection extended at a second operation in response to the histological findings. Histological examinations were always performed on 'representative sections'.

Follicular: Ten follicular carcinomas were treated during 1953–73. One other case was noted incidentally at post-mortem.

Three patients died from disseminated carcinoma, while a fourth died with a hemiplegia 2 weeks following operation (*Table XIII*). The 3 'tumour deaths' occurred in patients who presented with locally invasive carcinoma. Complete surgical excision was not possible and therefore radical radiotherapy was employed. Despite the resultant thyroid destruction, 2 patients never received thyroxine, while in the third (M. S., 1967) it was given only after the development of frank myxoedema. Clearly these hormone-dependent tumours were exposed to high levels of thyroid-stimulating hormone.

Two patients went on to develop metastatic carcinoma which has since been controlled. In both, carcinoma had extended locally and was eradicated by combined surgery and radiotherapy. Thyroxine was prescribed for one of these (J. J., 1958) only after the development of myxoedema. This patient had had a previous thyroidectomy for non-toxic multinodular goitre. The second patient (P. G., 1966) required tracheostomy for tracheal collapse 1 year after thyroidectomy. Locally invasive carcinoma was then discovered.

Only 4 patients remain recurrence-free. In these, carcinoma was confined within the thyroid capsule, facilitating complete excision. Clearly only one of this group (L. R., 1957) has been followed for any length of time, but it is significant that no patient with disseminated growth had tumour confined to the thyroid when first seen.

Anaplastic: Thirteen patients were treated for anaplastic carcinoma, while 4 others with advanced disease died rapidly with no treatment. With 3 exceptions, all the patients died within 5 months of presentation. Extensive local infiltration was a feature in all the cases. Seventy-five per cent of the patients developed systemic metastases.

Of the 3 patients who survived for longer than 5 months, one has since died at 3 years. This patient's carcinoma was atypical in exhibiting areas of both 'trabecular and follicular' pattern. The other 2 patients are alive with recurrent disease at 15 and 20 months. The latter has a 'fibrosarcomatous' tumour similar to those described by Woolner et al. (1961).

Mixed follicular-papillary: Only 6 tumours of this kind were recorded and one of these was noted incidentally at post-mortem. Four patients have remained recurrence free (average follow-up 8 years) following unilateral or bilateral subtotal thyroidectomy. Two of these, showing evidence of microscopic invasion, were in addition treated with external irradiation and thyroxine. The fifth developed local neck recurrence and deposits in her thyroidectomy scar. These have responded well to repeat surgery, radioactive iodine and suppressive doses of thyroxine. She is recurrence-free at 11 years.

Discussion

Carcinoma of the thyroid can present in several forms and it is certainly true to say that 'any goitre may be malignant' (Staunton and Greening, 1973). A percentage of these will be clinically apparent although estimates range between 10 per cent (Hurxthal and Heinemann, 1958) and 66 per cent (Till, 1965). It would appear that in specialized centres a preoperative diagnosis should be achieved in 50–60 per cent of all cases (Beahrs et al., 1951; Alhadeff et al., 1956; Shimaoka et al., 1962). The figure of 38·9 per cent reported in this series represents that of a non-specialist district general hospital.

Of great concern is the group of patients whose carcinoma presents in a form often indistinguishable from that of benign goitres; 61·1 per cent of patients in this series fall within this category. The recommendation of Shimaoka et al. (1962) that goitres should be classified as 'benign', 'cancer suspected' and 'cancer probable' would seem to be of value. In attempting to differentiate thyroid cancer from

Table XII: DETAILS OF PATIENTS TREATED FOR PAPILLARY CARCINOMA

				Treatment

benign goitre they achieved a high degree of correlation between actual and suspected cancer incidences.

When it was not possible to arrive at a histological diagnosis on purely clinical grounds the patients in this series were categorized as shown in *Table IV*. They were observed to have either a solitary nodule or generalized goitre, which was invariably non-toxic. The difference in behaviour of solitary nodule carcinomas and those presenting as multinodular goitre seems to suggest that they represent stages in a continuous process (*Table VII*). Cases not diagnosed at the solitary nodule stage may present later with a multinodular form.

It is well recognized that from 61·7 per cent (Rose et al., 1963) to 80 per cent (Clark et al., 1966) of unilateral thyroid cancers have demonstrable intraglandular dissemination. These microscopic foci may explain the transformation of a malignant solitary nodule into the multinodular form. Cases presenting at a more advanced stage are invariably diagnosed as carcinoma. This scheme applies to differentiated carcinomas only. The rapid progress of anaplastic tumours precludes the recognition of discernible stages. Occasionally a thyroid carcinoma may develop *de novo* in a pre-existing goitre (Burn and Taylor, 1962).

Solitary nodule carcinomas present on average 12 years before those in multinodular goitres. In this series they had been present for a mean of 23 months compared with the 6 years and 8 months of multinodular goitres. In addition, while multinodular carcinomas exhibit significant local and distant metastases, this is rare for solitary nodule carcinoma. The more advanced state of the multinodular carcinoma is reflected in its poorer prognosis. Thus, of 18 patients treated in this category, 6 have died while 4 others are alive with metastases. The survival figures shown in *Table VII* do not indicate the high incidence of metastases occurring in the patients. All the solitary nodule carcinomas responded well to treatment. Clearly it is important to recognize thyroid carcinoma during its solitary nodule phase, when cure may reasonably be attained.

Crile (in Discussion, Crile and Dempsey, 1949) suggested that a 'high index of suspicion' should be directed at all solitary nodules and was able to report a 90 per cent success rate in diagnosing carcinoma preoperatively in solitary nodules. In contrast, Hoffmann et al. (1972) stated that 'there is no way of differentiating benign from malignant solitary nodules and therefore all must be resected'; a view previously expressed by Liechty et al. (1965) and Taylor (1969b).

It is known that only 50 per cent of clinically solitary nodules are truly solitary (Taylor, 1969b). In these, cancer incidences reaching as high as 33 per cent have been recorded (Cattell and Colcock, 1953). The 2·7 per cent incidence reported in this series is lower than that of most other series as it relates to clinically solitary nodules only. This represents the cancer risk amongst patients subjected to thyroidectomy. The vast majority of operations for solitary nodules are therefore performed for benign nodules. Excellent results for solitary nodule carcinoma can only be achieved, however, if the surgery employed prophylactically is at the same time therapeutic for cancer (Crile, 1953). Prophylactic surgery is of no value if it results in local dissemination of incompletely removed carcinoma. Enucleation of solitary nodules as advocated by Lahey and Hare (1951) is clearly inadequate. Taylor (1965) and Shands and Gatling (1970) have recommended total lobectomy as the minimum procedure for solitary nodules.

Hinton and Lord (1945) and Beahrs et al. (1951) advocated the removal of all non-toxic multinodular goitres because of the high incidence of unsuspected carcinoma. The present study confirms this in reporting a 12·8 per cent incidence of carcinoma in non-toxic multinodular goitres. This figure, however, applies to surgical practice only. The incidence of carcinoma in non-toxic multinodular goitre amongst the general population is much lower than that seen surgically. Carcinoma incidences of 10 per cent (Cope et al., 1949), 10·9 per cent (Crile and Dempsey, 1949) and 17·1 per cent (Cole et al., 1949) have previously been reported in excised non-toxic multinodular goitres.

A major problem is the identification of the patients with non-toxic multinodular goitre who require thyroidectomy. Criteria helping to distinguish benign from malignant non-toxic multinodular goitres have been defined (Hurxthal and Heinemann, 1958; Sokal, 1959) in the belief that the removal of all goitres would result in more life lost than saved. Crile (1953) has stated that 'a woman with multinodular goitre would probably be better protected against the development of fatal cancer by removal of a normal appearing breast or cervix than by removal of the goitre'. While this may apply to the population at large, its relevance to the selected patients seen in surgical clinics is less clear. In this situation the processes of selection favouring cancer have a concentrating effect which may be as high as tenfold (Sokal, 1954; Veith et al., 1964). A decision not to operate on a non-toxic multinodular goitre can only be made in the knowledge that carcinoma has not been absolutely excluded. Patients seen in surgical clinics with non-toxic multinodular goitre should therefore be regarded as having selected themselves for surgery.

If total lobectomy is regarded as the minimal surgical procedure for the solitary nodule, then, it has been argued, total thyroidectomy must be the prophylaxis for multinodular goitre (Cope et al., 1949). Lesser procedures may in theory have resulted in local dissemination of carcinoma in 12·8 per cent of the patients seen in this series. Nevertheless, it would be irrational to advise total thyroidectomy, with its attendant complications, in all non-toxic multinodular goitres. A more realistic approach is the employment of bilateral subtotal thyroidectomy, with conversion to total thyroidectomy as needed. McKenzie (1971) has shown that total thyroidectomy eliminates the local recurrences seen to follow less radical operations. It has the added advantage of facilitating treatment with radio-iodine and prevents the transformation of differentiated into anaplastic carcinomas (Clark et al., 1966). In this series total thyroidectomy was not employed in the treatment of differentiated carcinomas and must, in part, be responsible for poor results obtained in the multinodular carcinomas. Wade (1969) has stressed the need to prevent local recurrence in the treatment of differentiated thyroid carcinoma.

Four tumour deaths were recorded amongst the differentiated thyroid carcinomas. All received external irradiation for locally invasive disease. In the single papillary carcinoma thyroxine was not introduced until systemic metastases appeared. Only 1 of the 3 follicular carcinomas received thyroxine and then only after the development of myxoedema. These tumours were clearly exposed to high levels of thyroid-stimulating hormone at a time when suppressive doses of thyroxine should have been employed. The hormonal dependency of differentiated thyroid cancer is now firmly established (Balme, 1954; Crile, 1966) following Dunhill's (1937) initial observation of tumour regression when treated with thyroid extract. It is imperative, therefore, that when dealing with differentiated thyroid carcinoma periods of hypothyroidism should be restricted to a minimum. This applies equally to carcinoma undergoing treatment with radioactive iodine (Crile and Wilson, 1959). A clearer understanding of the value of thyroxine, coupled with a wider use of total thyroidectomy, would have undoubtedly improved the prognosis amongst the patients reported in this series.

The prognosis of any cancer is determined primarily by its histological type and clinical stage. Good results obtained in treating differentiated thyroid carcinoma compare markedly with those obtained with anaplastic growths. While confirming this, the present study emphasizes the importance of clinical staging of the primary tumour. Clinically obvious carcinomas carry uniformly bad prognoses. They are invariably anaplastic as differentiated carcinomas reach this stage far less frequently. The slower growth of differentiated cancer usually results in them presenting at an earlier stage, when they may be mistaken for benign goitres. Differences in the pattern of behaviour of differentiated carcinomas at these early stages suggest that they pass through solitary nodule and multinodular forms before presenting the picture of a frankly malignant locally invasive goitre. These results emphasize the value of TNM staging when applied to thyroid cancer (Harmer, 1969). Fujimori (1969) was able to relate prognosis to the individual components of the TNM classification and clearly showed that increasing 'T number' was accompanied by worsening of prognosis.

Acknowledgements

We wish to thank Mr J. McKinnell, Consultant Pathologist, for reviewing the histological preparations and confirming diagnoses for all our patients.

Our thanks are also due to Miss J. Powell of the Regional Cancer Registry for her invaluable help, particularly in the preparation of data referable to the Birmingham region.

ETHICON
TRADEMARK
Eyeless needled sutures

REDUCE TRAUMA

ETHICON* Eyeless Needled Sutures offer three outstanding advantages over traditional eyed needles.

Point 1 Reduced trauma–with ETHICON eyeless needles there is no large eye and only one strand of material to pass through tissue.

Point 2 Consistent high quality–by precisely controlled manufacture of a complete sterile suture in a single package.

Point 3 A new sharp needle every time.

The choice is yours

Most surgeons agree that there is no universal suture. Most probably there never will be. Each patient, each procedure, and each layer of tissue differs from the next. This is why we at ETHICON manufacture such a comprehensive range of eyeless needled sutures.

You can choose from our wide selection of materials, absorbable and non-absorbable, securely attached to a stainless steel needle of your choice. The consistent high quality of ETHICON eyeless needled sutures provides predictable performance. This enables you to concentrate on the most critical aspect of your surgery–the well-being of the patient.

Motility changes in the antrum after proximal gastric vagotomy

MALCOLM KELLY AND TERENCE KENNEDY*

SUMMARY

The normal pattern of resting and post-prandial motor activity in the gastric antrum has been established by observations in 6 dogs. There was a gradual increase in the amplitude of contraction during the first 2 hours after eating; this was maintained for 3 hours and then declined. For the first 45 minutes terminal antral contraction occurred, partially retaining and triturating the gastric contents. After 45 minutes the waves became sequential, symmetrical, increased in vigour and actively pumped food into the duodenum.

Vagotomy modified the mechanism of the antrum in various ways. Truncal and selective vagotomy reduced the work capability to 20 per cent of its normal value when recorded 1 month after operation. In both groups the waves were disorganized.

Proximal gastric vagotomy abolished the braking mechanism and removed the initial inhibitory stimuli to antral motility. Within 1 month of operation the antrum had regained 58 per cent of its normal work capability and the contractions were well organized.

MOTOR denervation of the stomach is followed by a period of gastric paralysis the duration of which is unknown. This leads to gastric retention, distension and vomiting (Oberhelman and Dragstedt, 1955). Because of this difficulty the operation of vagotomy has been accompanied by a drainage procedure. In the case of pyloroplasty the delicate pyloroduodenal mechanism controlling gastric emptying is destroyed and can never be satisfactorily reconstituted; with gastro-enterostomy this region is simply bypassed. Either of these operations in combination with vagotomy converts a delicate storage and pumping mechanism controlled by fine neuro-facilitatory and inhibitory impulses into a denervated bag which empties precipitantly through a large hole in its wall. It is this transformation that produces the undesirable sequelae of dumping and diarrhoea following the operation of vagotomy and drainage.

In 1957 Griffiths and Harkins suggested that gastric stasis could be avoided after vagotomy if the nerves to the antrum were preserved. The production of acid by the stomach would be reduced by dividing the branches supplying the parietal cell mass only. However, the important antral pump would remain intact.

More recently, a number of centres (Amdrup and Jensen, 1970; Johnston and Wilkinson, 1970) have undertaken clinical trials of proximal gastric vagotomy, and follow-up data are accumulating, but there is no precise information about the changes in motility of the antrum after the operation. The present study investigated the motility in the normal animal before and after truncal, selective and proximal gastric vagotomy.

Method of studying gastric motility

Most of the present knowledge of gastro-intestinal motor activity is based on information from intraluminal pressure recording from balloons or open-tipped manometers (Wheelon and Thomas, 1920; Hightower and Code, 1950; Creamer et al., 1956; Harris and Pope, 1964; Edwards, 1965). Both methods are subject to artefacts due to transmitted pressure waves, interference with the flow of alimentary material or obstructed tubing. They are both difficult to locate precisely.

Because of these limitations a miniaturized mercury column strain gauge was developed for this investigation (Kelly et al., 1972). It consists of a fine silicone rubber tube filled with mercury under pressure (*Fig.* 1). As the tubing is stretched the column of mercury becomes longer and narrower, changing its electrical resistance. This in turn produces a signal which is amplified and recorded. Prior to implantation the gauges were calibrated in a waterbath at 37 °C to ensure a linear response over the working range of 4–6 cm.

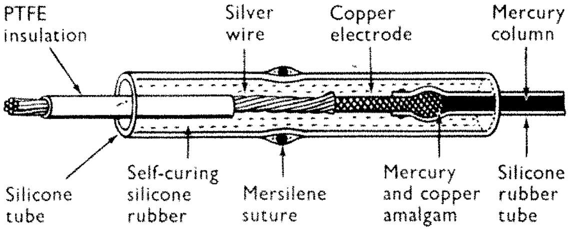

Fig. 1. The mercury strain gauge; transverse section through one end of a gauge showing the junction between the mercury, the wire and the electrode.

An *in vivo* trial was carried out on a small number of gauges to confirm that the response was both linear and meaningful. A latex balloon was placed in the stomach and inflated with CO_2. As the circumference of the antrum increased, the gauge increased in length, producing a corresponding pen deflection; this was compared with the actual measurement of the circumference and found to be directly linear (*Fig.* 2).

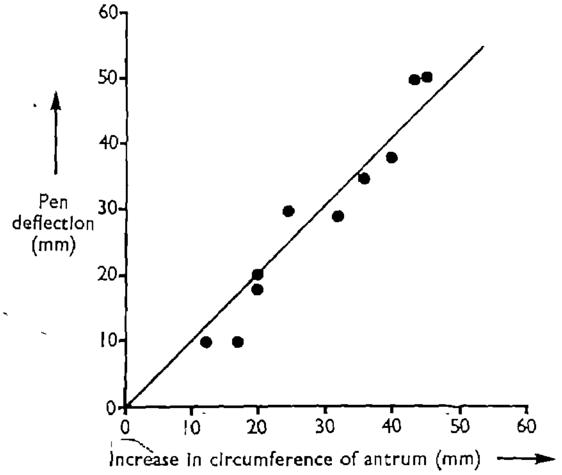

Fig. 2. *In vivo* calibration; graph of the increase in circumference of the antrum plotted against pen deflection on the Devices M19 recorder.

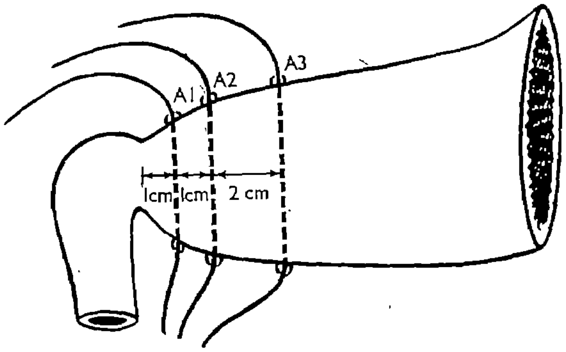

Fig. 3. Pyloric antrum and first part of duodenum showing the position of the gauges.

Implantation was carried out in sterile operating conditions under general anaesthesia. The gauges were accurately positioned on the serosal surface of the stomach at A1 (1 cm), A2 (2 cm) and A3 (4 cm) from the pylorus (*Fig.* 3) and sutured in place. An adequate length of wire was left in the peritoneal cavity; the ends of the wire were taken out through a stab wound in the right flank, and then subcutaneously to the dorsal surface of the neck. Here each wire was threaded on to a needle and brought out through individual puncture holes in the skin of the neck.

Vagotomy was performed at the same time as implantation, where this was appropriate.

Motility index and work capability

Motility recordings were made at weekly intervals after implantation of the gauges. The results at 1 month were used for comparison as they were found to be consistent and repeatable. Recordings made in the early postoperative period usually showed a disorganized pattern of varying amplitude. The dog was given a mixed meat meal and the recordings were continued for a 7-hour post-prandial period. A motility index was obtained from the trace every 15 minutes by measuring the total excursion of gauge A2 in mm over a period of 1 minute. A graph representing the total post-prandial motility was then plotted from these results.

In a number of the experiments the meal was mixed with barium powder and simultaneous radiological screening was performed. This enabled the gastric emptying to be directly related to the motility recording.

By measuring the area under the post-prandial motility graph it was possible to obtain a numerical representation of the amount of work performed by the antrum in the 7-hour period. Although the figure

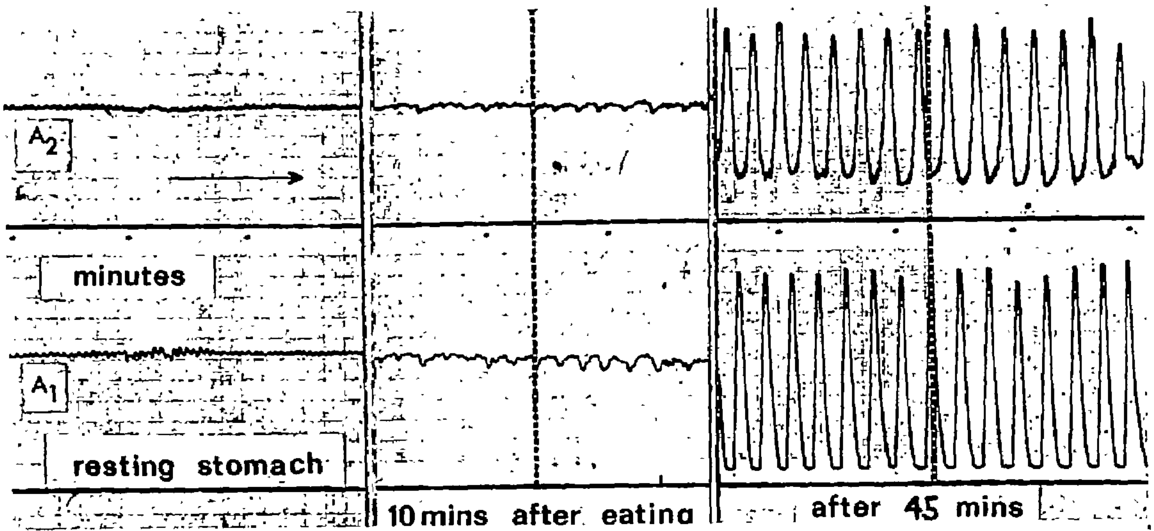

Fig. 4. Composite motility trace showing recordings from the stomach when resting, 10 minutes after eating and 45 minutes after eating. Shortly after eating, contractions at A1 and A2 occur simultaneously. A2 precedes A1 when emptying is well established.

was not an absolute value of work done in foot pounds it was nevertheless useful for comparing the work capability of the stomach after the various types of vagotomy.

Results

The normal stomach

Terminal antral contraction: Shortly after eating it was found that the gauges at A1 and A2 contracted simultaneously (*Fig*. 4), indicating that the terminal antral segment had contracted as a unit. Simultaneous radiological screening studies showed that food was predominantly retained at this time (*Fig*. 5). After 45 minutes the waves at A1 and A2 separated over the course of 5 minutes to become sequential and continued to increase in vigour. During this type of activity simultaneous radiological screening studies showed food being actively pumped into the duodenum.

Post-prandial motility contour: In the normal stomach (*Fig*. 6) there was a gradual build-up of motility for the first 2 hours after eating; this was maintained for 3 hours, then gradually declined. The hatched area under the graph represents the time during which terminal contraction was taking place and food was predominantly retained in the stomach. The dotted area represents sequential peristaltic activity when the food was actively pumped into the duodenum. The total area under the graph was taken as the total work capability of the normal antrum and represents 100 per cent activity.

After vagotomy

Nine dogs were subjected to vagotomy—3 truncal, 3 selective and 3 proximal gastric vagotomies. Strain gauges were implanted at the time of operation. One month later an insulin test was carried out to ensure that the vagotomy was complete, and motility was recorded.

After truncal vagotomy there was a dramatic decrease in overall motility and work capability of the antrum (*Fig*. 7). Not only was the amplitude of contraction diminished but the motility was disorganized. There were long periods of quiescence interspersed with bursts of activity (*Fig*. 8). This was quite unlike the regular high amplitude pattern seen in the normal stomach at this time. The total work capability was 22 per cent of normal. The changes following selective vagotomy were virtually identical (*Fig*. 9), the total work capability being 13 per cent of normal. When these animals were screened after a meal mixed with barium, the liquid part of the meal was seen to leave the stomach immediately, whilst the solid part remained for many hours.

After proximal gastric vagotomy the pattern was different. First, the overall motility was well maintained (*Fig*. 10). A most interesting feature was the speed with which high amplitude contractions occurred (*Fig*. 11). Within 10 minutes of eating they had reached their maximum values. In the normal stomach this was only attained 2 hours after eating. There was no initial period of terminal antral

contraction. From the moment food was taken simultaneous radiological screening studies showed sweeping waves pumping it into the duodenum. The total work capability was 58 per cent of normal.

Throughout the period of this study all the dogs in the proximal gastric vagotomy group remained in good health, maintaining or even gaining weight. Following selective or truncal vagotomy the dogs did less well, losing an average of 4·0 kg. Each study was concluded at 6 months and a post-mortem examination was carried out. There was no gross change in the antrum or pyloric ring of the proximal gastric vagotomy group, but in both the selective and the truncal groups the antrum was dilated and saccular, and the circumference of the pyloric ring was consistently greater than in normal dogs.

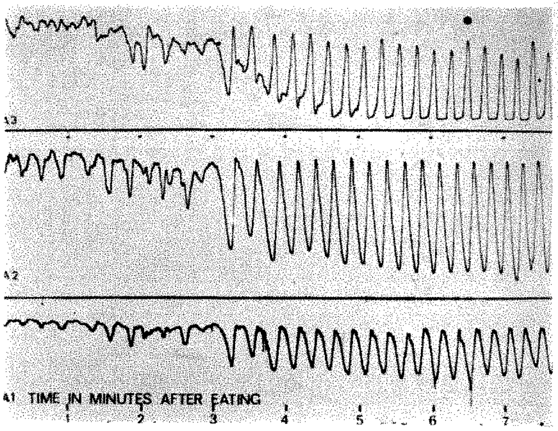

Fig. 11. Motility trace from gauges A1, A2 and A3 recorded 3 weeks after proximal gastric vagotomy. It shows that contractions have reached almost maximum amplitude within 7 minutes of eating.

Discussion

The operation of proximal gastric vagotomy is performed without a drainage operation. It aims to reduce gastric acidity and to allow the duodenal ulcer to heal whilst maintaining antral motility and effective gastric emptying. Does it achieve this? To confirm the effectiveness of vagotomy in this animal study, insulin stimulation tests were performed 1 month postoperatively. These were all negative according to Hollander's criteria. In a pilot study of 20 patients who underwent proximal gastric vagotomy in 1970 in the Royal Victoria Hospital, Belfast, the Hollander test was found to be negative in all the patients when measured on the tenth postoperative day. This was similar to the findings of Johnston and Wilkinson (1970).

The present investigation has shown that the avoidance of a drainage operation in combination with proximal gastric vagotomy maintains an active and effective pyloric pump which recovers rapidly after operation. This was in sharp contrast to the almost complete absence of motor activity seen after truncal and selective vagotomy. Stasis is unlikely to occur after proximal gastric vagotomy.

Without a drainage procedure the pyloric ring remains intact and will completely close at the end of each peristaltic cycle. This was first shown by Hofmeister and Schutz (1886) and by Moritz and Tschr (1901). It was confirmed by Cole (1913) and studied in detail by Quigley and Meschan (1941). The contracted pylorus not only provides a 'breach block' for duodenal contraction, but prevents the regurgitation of bile, a common problem after either pyloroplasty or gastrojejunostomy.

It was Cannon in 1898 who first pointed out that the pyloric region of the stomach had a more important function than that of merely expelling gastric contents into the intestine. He found that adding a hard pellet of starch to a gruel and bismuth meal given to a cat delayed gastric emptying from 15 to 45 minutes. Carlson et al. (1966), using cineradiographic techniques, described the mechanism through which this delay in gastric emptying was brought about. When peristaltic waves reach the antrum they produce a diaphragm which may or may not completely separate the antrum from the body of the stomach. At this moment a contraction involving the whole of the terminal antral segment, including the pyloric sphincter, occurs. Alimentary contents will be forcefully ejected into the duodenum until such time as the pyloric sphincter closes and prevents this flow. Since the pyloric canal is much narrower than the rest of the antrum it remains closed throughout the continuation of the terminal antral contraction. At other times the pyloric canal will narrow early in the cycle but not completely close so that movement of the contents through it into the duodenum occurs while the antrum continues to contract. This agrees with Hunt's (Hunt and Knox, 1968) theory of the regulation of gastric emptying, depending on the timing of the closure of the pylorus, during antral systole.

An unexpected finding in the present study was the complete absence of terminal antral contraction—and the 'antral braking mechanism'—after all types of vagotomy. Following a normal meal there is an initial period during which very little emptying occurs from the dog's stomach. The food is held back by a combination of contractions involving the terminal 3 cm of antrum, high antral tone and low amplitude peristaltic waves. The result of this is retropulsion of food into the body of the stomach. This capability is lost after vagotomy.

After proximal gastric vagotomy high amplitude peristaltic waves occur within minutes of eating, pumping the food into the duodenum with the result that a hypertonic meal could be delivered into the duodenum before equilibration, producing dumping. This finding has been confirmed in man by Clarke and Alexander-Williams (1973). They found that the initial emptying of a fluid meal was faster after proximal gastric vagotomy than in the normal individual. Dumping has been reported in various clinical trials (Humphrey et al., 1972; Clarke and Alexander-Williams, 1973). In our own pilot study 40 per cent of the patients admitted to mild transitory dumping at some time during the early postoperative period, but at 1 year after operation none had significant dumping symptoms.

The study has also thrown light on the phenomenon of dumping after the more conventional truncal and selective vagotomy. Again the braking mechanism was found to be completely absent after operation. Both radiological screening studies and post-mortem findings showed the antrum to be dilated and saccular, and the circumference of the pyloric ring to be consistently greater than in normal animals. It might be said that the denervated stomach behaves like the neurogenic bladder; if allowed to overdistend, as in the case of truncal and selective vagotomy without drainage, it becomes a dilated bag which empties by overflow.

Although the finer mechanisms of the antrum are disorganized after proximal gastric vagotomy, vigorous peristaltic activity remains, emptying is satisfactory and it is therefore unnecessary to perform an accompanying drainage operation.

The management of bleeding acute gastric erosions: the role of gastric hypothermia

H. S. HIMAL, W. W. WATSON, C. W. JONES AND L. D. MacLEAN*

SUMMARY

Eighty-eight consecutive patients with bleeding acute gastric erosions were reviewed with the aid of a computer. Of the erosions, 31·8 per cent were related to the ingestion of ulcerogenic drugs and 40·9 per cent were associated with surgery and sepsis. The overall mortality was 20·5 per cent. Endoscopy was the most effective diagnostic examination. Conservative management was effective in the treatment of bleeding erosions due to the ingestion of ulcerogenic drugs. Gastric cooling successfully arrested haemorrhage from bleeding erosions due to surgery and sepsis.

Massive haemorrhage from acute ulcerations of the upper gastro-intestinal tract is a formidable problem to manage. Most publications in the literature report a mortality of over 40 per cent (Capper and Buckler, 1964; Lulu and Dragstedt, 1970; David et al., 1971). Although first described early in the nineteenth century (Swan, 1823), Curling (1842) drew attention to the association between burns and acute gastroduodenal ulceration. Subsequent reports have emphasized the relationship between stress ulcers and surgery (Delaney, 1962; Fogelman and Garvey, 1966; Flowers et al., 1970), sepsis (Garvey and Fogelman, 1966; Rosoff and Goldman, 1968; Altemeier et al., 1972; Robbins et al., 1972) and chronic debilitating illness (Katz, 1959; Spencer et al., 1959, Fogelman and Garvey, 1966; Skillman et al., 1969).

A retrospective study of all forms of upper gastro-intestinal bleeding was undertaken by the authors to determine which factors were most commonly associated with mortality (Himal et al., 1974). The overall mortality was 12·54 per cent. The mortality rate correlated with the admission haemoglobin, the amount of blood administered, age and whether the preoperative diagnosis was known.

The present study was undertaken to analyse further, bleeding acute gastric erosions with respect to aetiology, efficacy of various diagnostic procedures and which of the management protocols was associated with the lowest mortality. The clinical impression that drug-induced, in contrast to sepsis-related, acute gastric erosions are associated with minimal mortality was also investigated. The effect of gastric cooling in the management of acute erosions was also assessed.

Materials and methods

Of 630 patients with upper gastro-intestinal haemorrhage seen between 1963 and 1971, 88 cases of bleeding acute gastric erosions were analysed. Each patient's chart was reviewed by one of the authors and the information collected was recorded on a standard data sheet as a 68-character line. This was transcribed via remote access terminal to a central processing and storage unit (IBM 360–75). Each character referenced a line of vocabulary according to its position. The data were processed using conventional set theory in Fortran IVG language. Analysis was carried out with respect to cause of erosions, accuracy of diagnosis and therapy.

Table I: CAUSES OF ACUTE GASTRIC EROSIONS

Initial insult	No. of patients	Mortality No.	Mortality %
Ulcerogenic drugs	28	1	3·6
Surgery and sepsis	36	11	30·5
Debilitating illness	10	4	40·0
Trauma	6	1	16·6
Unknown	8	1	12·6
Total	88	18	20·5

Table II: ACCURACY OF DIAGNOSTIC PROCEDURES

Procedure	No. of patients	Diagnostic accuracy No.	Diagnostic accuracy %
X-rays of the upper gastro-intestinal tract	30	5	16·6
Gastroscopy	50	47	94·0

Results

Causes of acute erosions

Of the 88 patients with bleeding acute erosions, 28 were caused by the ingestion of ulcerogenic drugs (acetylsalicylic acid, ethanol) and 36 were associated with surgery—neurosurgery, gastro-intestinal and cardiac surgery (*Table I*). Sepsis following gastro-intestinal surgery was an important factor. Ten patients had debilitating illness—hepatitis, multiple sclerosis and chronic renal failure. In 6 patients skeletal, spinal cord and blunt abdominal trauma were the predisposing factors. The overall mortality was 20·5 per cent.

Diagnostic procedures

Endoscopic examination of the stomach was the most accurate method of diagnosing bleeding gastric erosions (*Table II*). The accuracy rate was 94 per cent. Of 30 patients who had X-rays of the upper gastro-intestinal tract, in only 5 was there a suggestion of acute gastric erosions (16·6 per cent). At surgery in 12 patients and at post-mortem analysis in 6 patients

		Surgery	5	4
		Gastric cooling	—	—

examination revealed bleeding erosions. In 20 patients the only diagnostic assessment was clinical impression.

Management

All the patients had a short course of gastric saline lavage and intravenous therapy for resuscitation or maintenance while the initial diagnostic assessment was being made. Three different forms of therapy were used in this series.

1. *Conservative management*: Oral antacid therapy.
2. *Surgical management*: Operative intervention was the primary treatment.
3. *Gastric cooling*: This therapeutic approach was used only after an initial period of conservative management had failed to arrest the haemorrhage. A gastric balloon was placed per os into the stomach and gastric cooling by the Swenko* cooling machine was performed for 48 hours.

The overall distribution of therapy is displayed in *Table III*. The majority of patients (51) received only conservative therapy, with cessation of bleeding in 39 (76·4 per cent). Eight patients eventually died of their primary disease—malignancy, renal failure. Of 11 patients who had immediate surgery, 9 stopped bleeding. Six, however, died in the postoperative period of anastomotic disruption and localized sepsis. Of 26 patients who had gastric cooling, 22 stopped bleeding. The other 4 patients continued to bleed and therefore underwent surgery, but died of sepsis and haemorrhage.

The various treatment regimens in the different groups of patients are shown in *Table IV*. In patients with haemorrhage due to ulcerogenic drugs, all three forms of therapy were successful in stopping the bleeding. Gastric cooling was successful in patients with post-surgical or sepsis-related bleeding gastric erosions.

Discussion

Bleeding acute gastric erosions or gastritis have now become a prominent cause of upper gastro-intestinal haemorrhage (Foster et al., 1965; Garvey and Fogelman, 1966). Most reports indicate a greater than 30 per cent mortality from either continuous haemorrhage or postoperative complications (Fogelman and Garvey, 1966; Lulu and Dragstedt, 1970; David et al., 1971). The overall mortality in the present study was 20·5 per cent.

This study demonstrated that most bleeding acute gastric erosions (73 per cent) were related to the ingestion of ulcerogenic drugs, surgery and sepsis following surgery. Aspirin and ethanol alter the functional gastric mucosal barrier, increasing the net H^+Na^+ ionic flux, causing mucosal erosions and haemorrhage (Davenport, 1965, 1967). Localized and generalized sepsis can lead to thrombocytopenia, prolongation of the prothrombin time and an increase in gastric acid secretion (Rosoff and Goldman, 1968; David et al., 1971; Altemeier et al., 1972).

X-rays of the upper gastro-intestinal tract, when performed, suggested bleeding acute gastric erosions in only 16·6 per cent of the patients. Because of the shallow aspect of gastric erosions, contrast material frequently does not outline the mucosal defect.

Early endoscopy as the main diagnostic procedure for bleeding acute gastric erosions has previously been emphasized (Katz et al., 1964; Smith and Katon, 1973). In the present report endoscopy, when performed, demonstrated bleeding gastric erosions in 94 per cent of the patients.

Conservative management was most effective in the treatment of bleeding gastric erosions due to ulcerogenic drugs. In all 23 patients the haemorrhage stopped within 6 hours after initiation of antacid therapy.

Gastric erosions associated with surgery and sepsis was a difficult management problem. Conservative treatment led to cessation of haemorrhage in only 9 of 17 patients (53 per cent). Our preliminary experience with surgical treatment of these erosions led to a prohibitive mortality. The literature demonstrates a variable mortality. Flowers et al. (1970) in their series had a 23 per cent mortality, while Girvan and Passi (1971) had a 65 per cent survival rate.

Garvey and Fogelman (1966) reported a 66·7 per cent mortality with surgery. David et al. (1971) showed a greater than 30 per cent mortality with surgical management. Preliminary experience with gastric cooling indicated that this might be an effective therapeutic approach. Gastric hypothermia decreases blood flow through the stomach and duodenum as well as gastric acid secretion (Wangensteen et al., 1959; Peter et al., 1963). Decreased acid bathing the area and decreased blood flow would then favour healing of acute gastric erosions. Gastric cooling was employed in 26 patients and stopped the bleeding in 22 (84·6 per cent). Cooling was particularly effective in erosions associated with surgery and sepsis; the success rate was 84 per cent.

---

* Swenko Gastric Hypothermia Machine, Swenko Research & Development Inc., Minneapolis, Minnesota.

This study suggests that bleeding acute gastric erosions associated with ingestion of ulcerogenic drugs are effectively managed conservatively. Gastric cooling is effective in the management of erosions related to surgery and sepsis. Surgery has little if any role to play in the treatment of acute gastric erosions. Recent studies indicate that intra-arterial infusion of Pitressin may also be effective in the management of bleeding acute gastric erosions (Atharasoulis et al., 1974).

A case of haemorrhage from volvulus of the gastric fundus

C. METCALFE-GIBSON*

SUMMARY

Volvulus of the stomach is a rare condition and complications are even more uncommon. A case of haemorrhage complicating volvulus of the gastric fundus is presented.

Case report

W. M., a 60-year-old man, was admitted to hospital following a small haematemesis and the passage of a melaena stool. He was mildly shocked on admission, the pulse rate was 120 per minute, blood pressure 90/70 mm Hg and the haemoglobin was 10·3 g per cent. He responded satisfactorily to a 2-pint blood transfusion, and after 36 hours it was apparent that the haemorrhage had ceased.

His past history included a left phrenic nerve crush at the age of 19 for tuberculosis, and a myocardial infarction treated in hospital 4 months prior to the present admission. He did not give a history of indigestion but for 2 months before admission he had noticed an increased awareness of gastric fullness after taking fluids or small meals.

The chest X-ray on admission showed marked elevation of the left hemidiaphragm, some cardiac enlargement, fibrosis and calcified foci in the left upper lobe of the lung (*Fig.* 1). A barium meal performed 48 hours after admission showed an elevated stomach with a 'cup and spill' deformity but no evidence of peptic ulceration (*Fig.* 2).

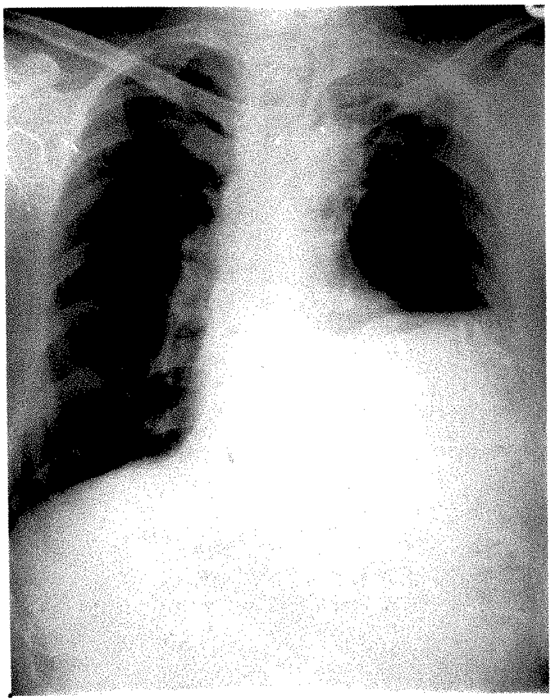

Fig. 1. Chest X-ray showing marked left diaphragmatic elevation.

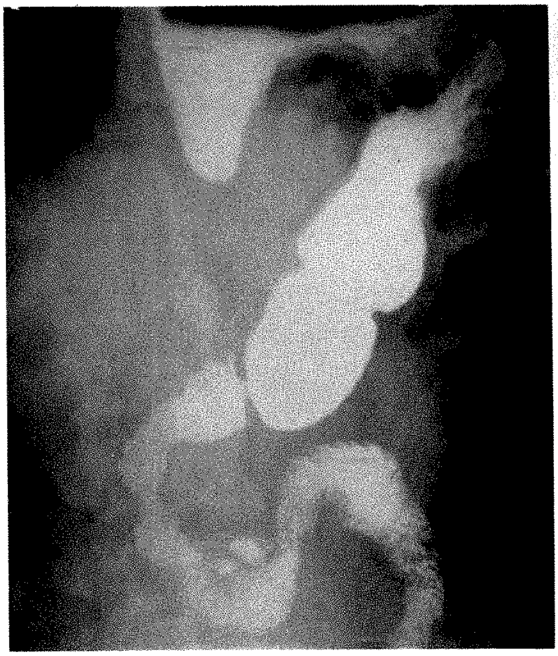

Fig. 2. Barium meal film showing 'cup and spill' gastric deformity.

Six days after admission the patient had a massive haematemesis and melaena and became severely shocked. The haemoglobin dropped to 8 g per cent, and despite an 8-pint transfusion over 3 hours the haemoglobin did not rise. There were difficulties at this stage in acquiring blood owing to the formation of antibodies and it was decided that a laparotomy was indicated.

The abdomen was opened through a right upper paramedian incision. The stomach was enlarged and lying more anteriorly than usual. There was no external evidence of peptic ulceration of the duodenum or anterior gastric wall. The duodenum was inspected through a duodenotomy and appeared healthy, but there was brisk haemorrhage coming from the stomach. The lesser sac was opened and it then became apparent that the gastric fundus had rotated posteriorly and was occupying the lesser sac, pushing the stomach anteriorly (*Figs.* 3, 4). Through a long gastrotomy it was possible to see haemorrhage coming from the opening into the retroverted fundus at the level of the oesophageal opening, but it was not possible to visualize its mucosa because of its fixation to the posterior abdominal wall. Three litres of blood clot and a number of undigested pea skins were retrieved from the fundus. In order to gain access to the fundus the duodenum was divided and the stomach mobilized as far as the oesophagus on the lesser curvature and to above the short gastric vessels on the greater curvature. By elevating the stomach vertically it was possible

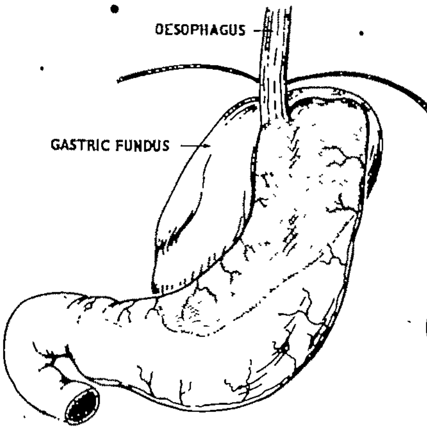

Fig. 3. Anterior aspect of stomach and gastric fundus.

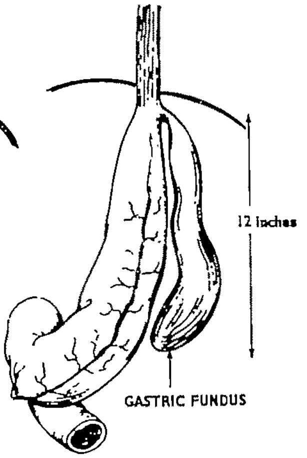

Fig. 4. Left lateral aspect of stomach and empty gastric fundus.

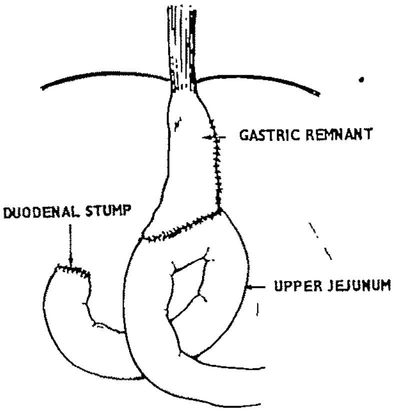

Fig. 5. Completed anatomy after fundectomy and gastrectomy.

to mobilize the fundus from the posterior abdominal wall by blunt dissection. By invagination of the fundus up through the gastrotomy it could be seen that the mucosa was replaced by multiple erosions. The fundus was excised on a level with the oesophageal opening and, as the antral region of the gastric remnant by this stage looked ischaemic, a Polya gastrectomy was also performed. The complete anatomy is depicted in *Fig.* 5.

The postoperative course was delayed by a transient jaundice and a prolonged left basal pneumonia. The patient was symptom-free and back at work at the 5-month follow-up.

Discussion

This case cannot be classified as a true volvulus of the stomach. Usually a volvulus requires the rotation of the greater curvature of stomach around the axis from the gastro-oesophageal opening to the pylorus (organo-axial) or in a plane at right angles to this (mesentero-axial). In the present case only the fundus was involved in a posterior organo-axial rotation.

Anatomical abnormalities associated with gastric volvulus have been summarized by Tanner (1968) and include ligamentous laxity, abnormal bands and adhesions, attraction to abnormal spaces, para-oesophageal hiatus hernia, congenital diaphragmatic hernias and eventration of the diaphragm. Ruckley and Fraser (1968) described a case of volvulus associated with leukaemic splenomegaly. Wastell and Ellis (1971), in their review of the world literature, showed that 80 per cent of cases occurred idiopathically and the remainder were related to anatomical defects. They included a case associated with an omental ball following previous surgery. In this case there was marked diaphragmatic elevation and the dimensions of the fundus were greatly increased. It is possible that the combination of these two factors was responsible for the volvulus.

Gastric volvulus may be asymptomatic or present as an acute surgical emergency with signs of acute obstruction or strangulation (Leading article, 1971). Haemorrhage as a presenting sign is rare, and the common symptoms are severe epigastric pain and Borchardt's triad (1904), namely vomiting followed by retching and finally inability to vomit, epigastric distension and inability to pass a nasogastric tube. Radiologically, barium fails to negotiate the oesophagogastric junction. In the present case none of these criteria was fulfilled and although barium passed into the stomach the true outline and dimensions of the fundus were obscured by the massive amount of blood clot that it contained.

It is postulated that the erosions were caused by stagnation as the pea skins retrieved at operation were eaten 10 days before surgery.

Technically, because the diaphragm and the stomach were elevated a thoraco-abdominal approach would have simplified access and mobilization of the fundus, and a gastrectomy may well have been avoided. In view of the previous tuberculosis, concomitant fibrosis and paralysed diaphragm it was considered that a thoracotomy would have imposed an excessive burden on an already extremely ill patient.

Acknowledgement

I should like to thank Mr G. R. Carr for his permission to publish this case and for his helpful advice and criticism.

Is 'second look surgery' justified in suspected recurrences of cancer of the stomach?

HAROLD ELLIS AND G. JAYASEKARA*

SUMMARY

A series of 23 patients with suspected recurrent disease following 'curative' resection for gastric carcinoma was submitted to further laparotomy (24 operations). Three patients were found to have hopeless dissemination, 10 had palliative procedures performed which relieved their dysphagia, vomiting and jaundice, 4 had recurrences resected and 1 had a second primary of the gastric stump excised. No less than 6 were found to have benign lesions.

Although the reward as far as prolonged survival is small, we believe that the relief of symptoms and the occasional long term excellent result justifies judicious use of a 'second look' laparotomy for suspected recurrent disease.

THE development of clinical features which suggest the recurrence of disease following what was believed to be a curative cancer resection is a depressing state of affairs which until recently was regarded by most surgeons as an entirely hopeless situation. However, in the past few years it has become increasingly recognized that some cancers have a tendency to local recurrence which may be controlled by further radical surgery, or that the apparent recurrence is in fact the development of a second primary metachronous tumour, which itself may be entirely operable. In some instances the clinical features may indeed be produced by altogether benign and curable situations, for example, a granulomatous stricture at an anastomosis. It is particularly in cancers of the colon and rectum that such favourable situations are likely to be found, and this we have recently reviewed (Ellis, 1974). However, most surgeons regard recurrent disease following resection of a gastric or oesophageal cancer as carrying a particularly poor prognosis.

This paper presents the results of a policy, carried out over the past 10 years, of re-exploring the abdomen for suspected recurrent cancer following 'curative' resections of gastric and oesophageal tumours in patients in whom the clinical features do not suggest that widespread hopeless dissemination of the disease had taken place. During this time 23 patients have been subjected to further laparotomy (24 operations). Of these, 20 had had their primary operation carrried out in the Surgical Unit, Westminster Hospital, and the remaining 3 were referred from other hospitals.

In carrying out this second exploration we had the following four possibilities in mind:

1. Could the clinical features be due to some altogether benign and remediable lesion?
2. If not, might a metachronous, resectable cancer have developed?
3. If indeed the tumour had recurred, could this itself be resected?
4. If the recurrence was unresectable, would a palliative short circuit or intubation to relieve obstruction be worth while?

Findings at operation

The findings in our 24 operations are shown in *Table I.*

Table I: FINDINGS AT 'SECOND LOOK' SURGERY

Finding:	No. of cases:
Benign lesion	6*
A second primary in the stomach	1
Recurrence in the gastric stump resected	3
Resection of ovarian secondary	1
Palliative procedure	10†
Laparotomy only	3

* One patient was subsequently re-explored for recurrence.
† One patient had undergone a previous laparotomy for a benign lesion.

Benign lesions mimicking recurrent disease (6 patients)

Two patients developed a benign stricture which radiologically mimicked recurrent cancer; both underwent re-resection. The first patient remains well 2 years following resection of his post-oesophagectomy stricture; the second died of disseminated cancer only 8 months after resection of his benign stricture following a total gastrectomy.

Two patients were re-explored for vomiting and pain which developed after partial gastrectomy. The first was found to have a benign stomal ulcer and was submitted to vagotomy; she remains well 4 years later. The second patient had a Roux conversion which relieved his symptoms but he developed disseminated recurrences and died 1 year following his second operation.

One patient presented with a mass in his abdominal scar, vomiting and loss of weight 5 months after total gastrectomy. The second laparotomy revealed that the mass was a sterile chronic abscess in the abdominal wall and his abdominal symptoms were produced by obstructing postoperative adhesions affecting the upper jejunum. These were divided and he remained well for 4 years. He then developed an anastomotic recurrence with dysphagia. This was treated by a Souttar's tube intubation and he died 1 month following this.

One patient from Cyprus presented with vomiting and dysphagia 4 months after an upper partial gastrectomy for a carcinoma of the cardia performed at another hospital. At laparotomy there was no evidence of recurrent disease. A pyloroplasty was performed and her symptoms disappeared. The patient returned to Cyprus and has been lost from our follow-up.

---

* Surgical Unit, Westminster Hospital, London.

In this group 3 patients achieved reasonably long term satisfactory results, 2 of whom are still living, 2 patients developed recurrences quite rapidly and 1 has been lost to follow-up.

A second primary in the stomach
There was 1 example in this series of an undoubted metachronous primary in the stomach. This was a female patient who in 1943, at the age of 43, had a partial gastrectomy for a spheroidal cell carcinoma of the stomach. She returned in 1967 at the age of 67 with a tumour mass in the gastric stump and an abdominal total gastrectomy was performed. Histological examination revealed a highly anaplastic carcinoma which did not resemble the appearance of the original tumour. The lymph nodes were extensively involved. Local recurrences rapidly developed and she died 6 months after her second operation.

Resection of recurrences (4 patients)
Three patients developed local recurrences which were resectable; 1 after partial gastrectomy and 2 after total gastrectomy. The partial gastrectomy was converted to total gastrectomy but recurrences developed and the patient died 11 months later. One of the patients who had undergone total gastrectomy died only 4 months after resection of the anastomotic recurrence. The other patient remained well for 20 months following this procedure; he then developed a further local recurrence which was treated by radiotherapy and he has remained clinically free from disease for 3 years.

The fourth patient developed an ovarian metastasis 1 year after her partial gastrectomy. This was resected but she died 14 months later with widespread metastases.

Only 1 of the 4 patients in this group has had reasonable long term benefit from surgery although 2 others were relieved of their dysphagia.

Palliative operations (10 patients)
Four patients with dysphagia due to local recurrences following partial or total gastrectomy had the obstruction intubated by means of a Porge's or Souttar's tube. Although dysphagia was relieved, these patients died 3 weeks, 3 weeks, 6 weeks and 2 months respectively following the procedure.

In 3 patients a gastro-enterostomy was performed to the gastric stump; obstructive symptoms were relieved but the patients died 3, 5 and 8 months respectively following surgery.

Three patients developed obstructive jaundice due to tumour masses in the porta hepatitis and it was possible to short-circuit the distended gallbladder to the jejunum. Jaundice was relieved but the patients died 6 weeks, 2 months and 7 months respectively after this second operation.

Laparotomy only (3 patients)
In 3 patients laparotomy was performed with the discovery of widespread intra-abdominal dissemination. One patient died 4 days postoperatively. The others were treated with 5-fluorouracil but died 7 weeks and 7 months respectively following laparotomy.

Discussion

Results of previous re-exploration programmes
An important stimulus to surgical thinking on the problem of recurrent abdominal cancer was the interesting and controversial work of Wangensteen, who introduced his 'second look' programme in 1948 (Wangensteen, 1949). In this experiment, patients who had undergone what was considered to have been curative resection of the stomach or large bowel, and in whom the regional lymph nodes were found to be involved on histological examination, were re-explored approximately 6 months later. At this 'second look' any recurrence of cancer, if found, was resected if this was technically possible. Subsequently, similar operations were performed on the patients in whom further tumour had been found and resected, and these were repeated at intervals of 6 months to 1 year until either no further tumour was discovered or the situation was obviously out of control. Once the patient had had an exploration which revealed no residual cancer, further laparotomy was not performed but careful follow-up was continued. Within a few years it was obvious that although results of re-exploration in colonic cancer were encouraging, rectal cancer recurrences tended to be diffuse and reoperation in gastric cancer was difficult and far less rewarding (Wangensteen et al., 1954).

An extensive survey of the results of this programme up to July 1967 was published by Griffen et al. in 1969. In the group of patients with carcinoma of the stomach 64 were submitted to re-exploration. Twenty-eight of these had a negative 'second look', of whom 10 subsequently developed recurrent cancer, 7 died of other causes and 11 remained alive and well. Of 37 patients with positive 'second look' operations, there were 3 operative deaths, 1 patient died of causes other than cancer and 31 developed further recurrent disease. Only 2 patients were alive and well and could therefore be considered to have been 'converted' to this state by the additional resection. In this study a further 37 patients were reported who presented with symptomatic recurrent disease and were re-explored; none of these was converted to a cancer-free situation. These figures therefore gave no support to a continued programme of elective re-explorations in gastric cancer.

In the past 20 years there have been other important studies of series of recurrent gastric carcinomas subjected to further laparotomy with re-resection, where this was possible. In addition to these reviews there has been a considerable number of individual case reports. These papers, on the whole, paint a gloomy picture of the prognosis following a further resection, but there are occasional brilliant results with survival of 5 or more years following the second operation.

Bowden et al. (1954) described 37 patients who were re-explored for recurrent gastric carcinoma; in 15 a further resection was carried out. There were 2 postoperative deaths. Of the 13 recovering from surgery, 8 patients survived an average of 8 months, 2 were alive with metastases, 2 were alive and clinically clear of disease at 15 and 18 months and 1 patient was alive and well 5 years and 10 months following the second operation. Of the 22 patients in which further resection was impossible, 4 underwent palliative procedures. The average survival in these 22 patients was 6 months with a range of 1–20 months. Welch and Wilkins (1958) carried out 7 'second look' gastric cancer operations; in 4 it was possible to carry out further resection, and although 2 of the patients died postoperatively, the other 2 lived for 5 years after the second operation. It is interesting that neither of these had positive lymph nodes at either laparotomy. Funderburk (1962) collected reports on 53 patients undergoing reoperation for cancer of the stomach, including 2 of his own cases. Resection was possible in 24 of these patients, with survival of 4–70 months; 6 lived for more than 18 months. One of his own patients had a partial gastrectomy in 1946 which was converted in 1957 to total gastrectomy for recurrence. In 1961 she had a third operation in which a malignant node in the jejunal mesentery was resected and she was alive at the time of reporting. Ferguson and Nusbaum (1963) reviewed 94 patients undergoing primary surgery for cancer of the stomach; 93 were explored and 48 underwent radical gastrectomy. Two of these were subsequently re-explored for recurrent disease; one recurrence was resected 7 years later and the patient was well 4 years after the second operation; another patient developed a metastatic lesion in the colon which was resected 8 years after the initial surgery, but the patient died 3 years later of recurrent disease. Lippert (1968) reported 5 cases of reoperation for gastric cancer; 3 underwent radical re-resection; 1 of these died 3 years after the second operation, but the other 2 were alive at 4 and 7 years. The fourth patient underwent a decompression operation for common bile duct obstruction and died 30 months later. The fifth patient underwent a total of 4 'second look' procedures over the course of 2½ years—resection of small bowel, removal of deposits first in the left and then in the right ovary and finally an ileotransverse colon bypass operation. The patient died 2 months after the short-circuit procedure.

Iwasa et al. (1972) have recently reported an extensive study of operations for recurrent gastric cancer in Tokyo, with overall discouraging findings; 109 patients were seen between 1956 and 1971 with recurrent tumours. Of these, 58 were submitted to a second laparotomy. Four only were suitable for further resection and only 1 of these survived for 2 years. Fifteen patients were submitted to laparotomy only, and the rest had various palliative procedures, including bypass or feeding jejunostomy. Most of these were dead within 1 year.

An extraordinary case was reported by Aviles (1973); this woman underwent a right hemicolectomy for carcinoma in 1942, a resection of a second tumour in the sigmoid colon in 1946, a partial gastrectomy for a carcinoma of the stomach in 1960 (at which time the lymph nodes were clear) and in 1967 a total gastrectomy for recurrence in the stump. The patient recovered from this procedure but no further information was given about her subsequent progress.

Tumour implantation

It is well known that tumour cells may seed into the wound at the time of operation (Ryall, 1907). Such deposits may occur not only after surgical exploration but even at the site of paracentesis for malignant ascites (Bush, 1957). Such implantation may be widespread throughout the abdominal wound and peritoneal cavity, but occasionally isolated deposits may develop which are suitable for excisional surgery. Ackerman and Wheat (1955) described a patient who was well 4 years after a resection of a tumour mass in the abdominal scar which developed 1 year following resection of a gastric carcinoma. Sonneland (1959) resected a scar deposit 2 years after gastrectomy for a carcinoma of the stomach. The patient was alive 1 year later but had liver deposits. Fortner and Lawrence (1960) reviewed the extensive experience at the Memorial Hospital for Cancer, New York. 'Curative' gastric resections were carried out on 569 patients between 1931 and 1957. Eleven of these subsequently developed a lump in the laparotomy scar and it is interesting that 2 of these were benign, one being a desmoid, the other an inflammatory mass. Of the 9 secondary deposits, 3 were excised, 2 had radiotherapy and 4 had no local treatment. All these patients died with carcinomatosis 3–28 months after the recurrence.

In 1958, in a survey of 31 patients having laparotomies for suspected recurrent cancers, we reported a patient who had recurrences removed from the abdominal scar 7 and 17 months following resection for gastric carcinoma. Four months after the second recurrence had been removed she developed deposits in both axillae which were excised; she died some months following this from carcinomatosis (Cronin and Ellis, 1958).

A striking long term survival was reported by Inouye and Erb (1965); this was a patient who underwent a partial gastrectomy in 1945, developed a deposit in his abdominal incision 3 months later and then survived after its excision for 17 years until 1963, when he developed a recurrence in his gastric stump and died following further resection.

Metachronous cancer in the gastric stump

A second carcinoma developing in the same organ is a well-recognized phenomenon, particularly in squamous and basal tumours of the skin, in carcinomas of the large bowel and, in a slightly different context, in the opposite breast following mastectomy. A second primary cancer may also undoubtedly develop in the gastric stump following partial gastrectomy for malignant disease. In this situation the development of a second primary tumour must be differentiated from recurrence of the original disease, and can be made on the grounds either that the two tumours are quite distinct in histological appearance or that the interval between the appearance of the two tumours is sufficiently long to make recurrence of the original cancer unlikely. Morgenstern (1960), in presenting 2 such patients, was able to review 11 previously reported cases. Five of these had no follow-up, 5 died at intervals of up to 14 months following operation and 1 patient lived for 7 years after the second resection (Stoloff and Lattimore, 1955).

In a later paper Morgenstern et al. (1973) were able to add 2 more patients to Morgenstern's original experience. They considered that a gap of no less than 20 years should elapse between the two tumours in differentiation between recurrence and a second primary cancer, although other authors accept a gap of 10 years. Of the 4 patients reported, 1 initially had a partial gastrectomy for a reticulum cell sarcoma and died 4 years after resection of an adenocarcinoma arising in the stump 25 years after the initial operation. The other 3 patients, all of whom had an initial carcinoma of the stomach and who subsequently developed a second tumour 22, 25 and 30 years later respectively, underwent further resection. There was 1 postoperative death, 1 patient died 2 years after the second operation and 1 patient was still alive and well 5 years later.

Obviously, the development of a second cancer of the stomach following partial gastrectomy is an unusual occurrence, probably related, at least in part, to the fact that prolonged survival following gastrectomy is unfortunately an infrequent phenomenon. In the patient we reported the interval between the two operations was 24 years and the histological appearance of the two tumours was entirely dissimilar so that undoubtedly this represented a metachronous primary cancer. Unfortunately rapid recurrence and death followed the second resection.

Conclusion

Carcinoma of the stomach remains one of the most dangerous of the major cancers and is the third commonest cause of death from malignant disease in the United Kingdom. In patients undergoing what is thought to be curative resection, large numbers present with obvious clinical recurrent disease within 5 years.

There is a general feeling among surgeons that when recurrence or metastases are diagnosed following gastric resection the situation is a hopeless surgical proposition. A review of previous publications and of our own experience confirms that the outlook is indeed gloomy, but by no means hopeless. In the 23 patients we have operated upon over the past 10 years (24 operations) 3 had a laparotomy only, confirming a hopeless situation. Ten had palliative procedures for obstructive jaundice, gastric outlet obstruction or dysphagia, and all of these died within a few months, although useful palliation had been achieved from these unpleasant symptoms. Four patients with recurrent or metastatic disease were suitable for resection, but only 1 achieved 3 years of relief of his dysphagia, and this period included a course of radiotherapy for further recurrent disease. One patient with an undoubted metachronous lesion in the gastric stump died 6 months after further resection. However, it must be noted that from time to time encouraging long term survivals have been reported following re-resection of recurrent, metastatic and metachronous cancers after gastric resection.

Perhaps the brightest ray of encouragement is our finding that no less than 6 of our patients who were considered clinically to have developed recurrent disease were found to have benign lesions at laparotomy. One has been lost to follow-up, 2 are well 2 and 4 years after surgery respectively, but the remaining 3 developed frank recurrent disease and died 8 months, 1 year and 4 years respectively following the finding of a benign lesion at their 'second look' procedure (the last patient having intubation performed for his recurrent tumour).

In spite of this small reward we conclude that a laparotomy is still justifiable in a patient who develops clinical evidence of apparent recurrent disease following 'curative' resection for gastric cancer. Rarely an altogether benign lesion can be found and cured, and perhaps this alone is worth all the endeavour. Occasionally a recurrent or metachronous lesion can be resected with long term cure, although this was not our own experience in this small series. There is no doubt that in many cases unpleasant symptoms (dysphagia, gastric outlet obstruction and jaundice) can be relieved up to the time of the patient's death, even though this may be measured only in months or even weeks.

However, even if nothing at all can be done at the time of surgery, at least the diagnosis can be confirmed without any doubt, a decision made as to whether or not cytotoxic drugs should be employed and, perhaps most important of all, the patient's family and the patient himself can realize that no stone has been left unturned before the final hopeless prognosis has been given.

Flatulent dyspepsia in patients with gallstones undergoing cholecystectomy

R. D. KINGSTON AND C. W. O. WINDSOR*

SUMMARY

The incidence of flatulent dyspepsia and its relationship to gallbladder function has been studied in 100 consecutive patients with gallstones undergoing cholecystectomy. Thirty-three per cent of patients suffered significant flatulent dyspepsia of whom 80 per cent were cured or improved by operation.

In 15 patients gastric function was studied pre- and postoperatively and it was noted that there was no difference in gastric emptying times between patients with flatulent dyspepsia who were cured by operation and those who remained symptomatic.

Bacteriological studies on gallbladder bile from 39 patients suggested that infection within the gallbladder may be a factor in the causation of flatulent dyspepsia.

IT is not uncommon to have to decide whether the removal of a non-functioning gallbladder will cure the symptoms of flatulent dyspepsia or conversely whether cholecystectomy will cure flatulent dyspepsia in a patient with a normal cholecystogram. These difficulties arise because the symptom complex known as flatulent dyspepsia is often ill-defined and because the cause of the symptoms is not fully known. Certain of the clinical features—fullness after meals, distension and nausea—are suggestive of gastric retention, whilst others—retrosternal discomfort and bilious vomiting—suggest oesophagitis and a hiatus hernia.

In this study gastric emptying has been measured before and after cholecystectomy and the findings related to the symptoms of flatulent dyspepsia. Also, correlations between other factors such as gallbladder function and biliary infection have been sought.

Materials and methods

This is a prospective study of 100 consecutive patients undergoing cholecystectomy for gallstones. There were 75 females and 25 males. The average age was 53 years with an age range of 17–80 years. The follow-up was between 3 months and 3 years with a mean of 13 months. All the patients were interviewed pre- and postoperatively.

A patient was considered to have flatulent dyspepsia if three or more of the following symptoms were consistently present to a moderate or severe degree. A combination of the last three symptoms *only* was not classified as flatulent dyspepsia.

Symptoms

Flatulence: Repeated belching; full feeling after a normal-sized meal; inability to finish a normal-sized meal; abdomen becomes blown out so that clothes need to be loosened.

Dyspepsia after meals: Burning discomfort in the epigastrium; burning discomfort in the chest; vomiting or nausea.

All symptoms were noted preoperatively and at review 3–12 months postoperatively.

Gallbladder function was assessed by oral cholecystography in 83 patients; Biliodyl (phenobutiodil) 0·3 g/kg body weight was given 12 hours before X-ray.

Bile from the gallbladder in the last 39 patients in the series was sent directly from the operating theatre for culture.

Pre- and postoperative gastric emptying times were measured in 15 patients: 5 flatulent dyspeptics who were cured by operation, 5 who were not cured and 5 patients not suffering with flatulent dyspepsia. The patients ate a meal consisting of two slices of bread and butter (1 oz), two scrambled eggs, a cup of tea and 30 ml of Raybar (barium). The ingredients were liquidized. After ingestion X-rays were taken at 15-minute intervals for 2 hours and 30 minutes thereafter. Three times were recorded: (*a*) the start of gastric emptying; (*b*) the time when the head of the meal reached the caecum; (*c*) the time when gastric emptying was completed.

The patients were encouraged to sit in a chair or to stroll about in the intervals between X-rays. The postoperative measurements were made between 6 and 12 weeks after operation.

Table I: REFERRING SYMPTOM

Symptom:		No. of cases:
	Acute cholecystitis	52*
	Biliary colic	28
	Jaundice	11
	Flatulent dyspepsia	4
	Incidental	3
	Pancreatitis	2
	Total	100

* Four perforated gallbladders.

Results

A review of the symptoms leading to the patients' referral is shown in *Table I*, only 4 per cent of patients presenting primarily with flatulent dyspepsia. However, 33 of the 100 patients reviewed had significant flatulent dyspepsia, and 27 (80 per cent) of these were cured or improved of their symptoms by cholecystectomy.

Analysis of gallbladder function in the two main groups of patients—flatulent dyspeptics and non-dyspeptics—reveals that there were more functioning than non-functioning gallbladders in the patients with

Table IV: BACTERIOLOGICAL FINDINGS OF BILE CULTURED FROM THE GALLBLADDER IN 39 PATIENTS

Group	Infected bile	Non-infected bile
Dyspeptics	8	5
Non-dyspeptics	13	13
Cured dyspeptics	7/8	—
Non-cured dyspeptics	0/5	—

flatulent dyspepsia (*Table II*). Further, in comparing gallbladder function (*Table III*) in dyspeptics cured by operation and those remaining symptomatic postoperatively there were more functioning than non-functioning gallbladders in patients who were cured of their dyspepsia. In neither group, however, is the difference statistically significant ($\chi^2 = 1{\cdot}91$, 0·6, 0·46, 0·97).

Table IV correlates the symptoms of flatulent dyspepsia with the bacteriological findings of the bile taken at operation from the gallbladder. In the non-dyspeptic group equal numbers of patients (13) had infected and non-infected bile. In the dyspeptic patients 8 patients had infected bile and 5 had sterile bile. Seven out of 8 patients cured of their dyspepsia by operation had infected bile, whilst the bile was sterile in those whose symptoms remained (5 patients).

Fig. 1 shows the results of the gastric emptying studies in the three groups of patients studied pre- and postoperatively—those cured of flatulent dyspepsia, those not cured of flatulent dyspepsia and a group of patients not having symptoms of flatulent dyspepsia. Five patients were studied in each group and the results are the means of the times. Gastric emptying (column 1) commenced in the first 15 minutes in all groups and was not influenced by operation. Column 2 shows the times taken for the meal to reach the ileocaecal valve. Cholecystectomy seemed to increase this transit time, particularly in patients whose dyspepsia was not improved by operation. Column 3 shows the time taken for complete gastric emptying, which is similar in all three groups and not altered postoperatively except slightly lengthened in the non-cured dyspeptics. In summary, there was no significant difference in emptying times in the three groups studied and operation made very little difference to the emptying times.

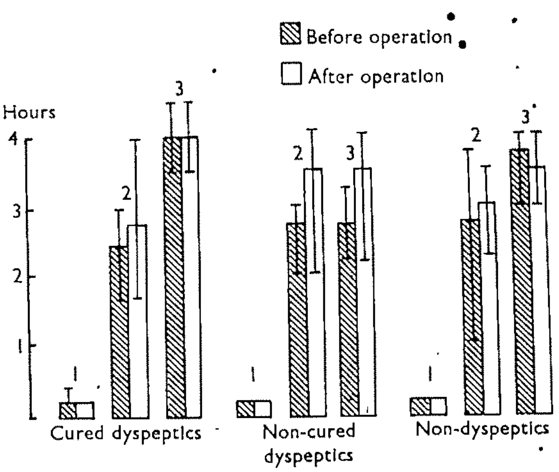

Fig. 1. Gastric emptying times before and after operation in patients who were cured of flatulent dyspepsia by operation, those not cured by operation and patients without symptoms of flatulent dyspepsia.

Discussion

In 1971 Johnson performed a pre- and postoperative symptomatic review of 108 patients undergoing cholecystectomy and related his findings to gallbladder function. He found that preoperatively 83 per cent of his patients suffered with flatulent dyspepsia, which is at variance with our figure of 33 per cent. The explanation is probably that we have been more selective in our choice of patients with flatulent dyspepsia, by excluding those with mild dyspepsia and those with dyspepsia only related to acute cholecystitis. Our objective was to select only patients with a definitely abnormal degree of flatulent dyspepsia.

Our cure or improved rate is similar to that in Johnson's series but not in agreement with Maingot's (1956) statement that cholecystectomy has little or no effect in curing the unpleasant symptoms of flatulent dyspepsia.

Johnson (1971) made two further points: that functioning gallbladders were more common in patients cured of their dyspepsia, and that since removal of the gallbladder cures or improves the majority of patients then the underlying cause must be gallbladder disease. Our findings are in general agreement with these points, but the number of functioning gallbladders in our cured dyspeptics is not statistically significantly higher than that of non-functioning gallbladders.

Capper in 1967 studied pyloric function in patients undergoing cholecystectomy before and after operation by intubation tests and showed that a duodenum distended with bile predisposed to delayed gastric emptying and bile regurgitation (Capper, 1967; Capper et al., 1967). Further, at gastroscopy on these patients he noted a high incidence of gastric atrophy. Johnson (1972) studied pyloric function in three groups of patients—patients with cholelithiasis with and without flatulent dyspepsia and patients with normal cholecystograms and no dyspepsia. He used a modified pyloric regurgitation test, assessing function radiologically and biochemically. A close correlationship between the symptoms of flatulent dyspepsia and pyloric regurgitation was noted in all three groups.

It was these findings which encouraged us to measure gastric emptying times in the three groups of patients and to assess any postoperative difference. The method we used is a simple physiological one which will demonstrate quite small differences in emptying rates. Humphrey and Williamson (1972) using the same technique showed significant differences in gastric emptying times in patients after highly selective, selective or truncal vagotomy. The fact that we did not elicit any difference in emptying times may possibly be accounted for by lack of sufficient stimulus in the meal and the fact that we examined patients in 'remission'. With regard to the periodicity of symptoms it became apparent to us during our study of patients' symptomatology that flatulent dyspepsia in patients with gallstones has exacerbations and remissions. At times dyspeptic patients may comfortably tolerate high fat content meals. In a separate study we fed individual patients up to ten graded fatty meals preoperatively and assessed their dyspepsia. Some patients consistently tolerated high fat meals and yet had suffered severe exacerbations of flatulent dyspepsia previously. It is regretted that only 15 out of the 100 patients underwent gastric emptying studies but in a busy general hospital facilities were not available to study more patients. However, further studies of emptying times are being performed, varying the type of meal, the symptomatic condition of the patient and possibly the method of measurement.

The finding that 7 out of 8 patients with flatulent dyspepsia and infected bile were cured by cholecystectomy is suggestive that infected bile is a factor in the causation of flatulent dyspepsia. Against this is the fact that half of the non-dyspeptic patients had infected bile. It may be a matter of degree and a certain type or level of infection needing to be present before becoming significant in producing flatulent dyspepsia. There did not appear to be a predominant organism responsible for infection in the bile. In 50 per cent of cases a mixed growth was present. *Escherichia coli* was present in 50 per cent of the total either alone or mixed. Streptococci (non-haemolytic and faecal) were present in 40 per cent of the total. There was a wide variety of other organisms isolated, mainly in individual cases.

Infected bile as a significant factor obviously requires further study, but the concept of a functioning gallbladder emptying infected bile into the duodenum producing an ileus with reflux of bile into the stomach would appear to be a very possible cause of flatulent dyspepsia. The fact that infection may be present in a gallbladder without producing signs of acute cholecystitis is supported by the frequent post-mortem and operative finding of chronically infected fibrosed gallbladders which were unsuspected in life.

In assessing the results of cholecystectomy we noted that 9 out of 10 patients with flatulent dyspepsia and a non-functioning gallbladder were cured or improved by cholecystectomy. Similarly 14 out of 17 patients with flatulent dyspepsia and a functioning gallbladder containing stones were cured or improved by cholecystectomy.

However, during the period of this survey as a result of deliberate policy 6 patients with functioning gallbladders but no stones (therefore not included in this series) having severe flatulent dyspepsia underwent cholecystectomy. In only 2 were the symptoms improved.

Traumatic haemobilia

E. VALLIDIS AND N. PAPALEXANDRIS*

SUMMARY

A case of traumatic haemobilia which was diagnosed preoperatively, is reported. The site of bleeding was demonstrated by operative angiography through the right hepatic artery. The patient was treated by ligation of the common hepatic artery. Re-bleeding required a second operation and ligation of the right hepatic branch without adverse consequences on the hepatic function.

Case report

A 37-year-old man fell off a crane from a height of about 30 ft on the island of Crete. He sustained fractures of the 8th, 9th, 10th and 11th right ribs, rupture of the right lobe of the liver, rupture of the right diaphragm and contusion of the base of the right lung. He was operated on at the local hospital and the ruptured liver and right diaphragm were sutured. His postoperative course was stormy. On the eighth postoperative day he developed jaundice and on the fourteenth day he had melaena which was repeated 2 days later. Twenty-five days after the accident (July 1973) the patient was transferred to the Red Cross Hospital in Athens for further investigation and treatment.

On examination he was found to be in a relatively good general condition with a pulse of 84/minute and a blood pressure of 120/80. He was of light build and slightly pale and his wounds were healed. There was a drain under the right costal margin packed with gauze.

Laboratory investigations showed the following: haemoglobin 86 per cent, ESR 57–83 mm/h, serum bilirubin 2·20 mg per cent, WBC 9600/mm^3, blood urea 0·35 g per cent and urine analysis normal. The chest X-ray demonstrated no other abnormality than fractures of the right 8th–11th ribs with slight displacement of the fractured ends.

On removal of the drain about 1 litre of fluid came out consisting of dark blood, pus, bile and tiny pieces of liver tissue. Culture of the fluid disclosed coliforms sensitive to gentamycin. The body temperature fluctuated from 39·2 to 37·2 °C during the first fortnight after admission.

While the patient's condition was steadily improving and the discharge was diminishing, he suddenly complained of a very severe pain in the right hypochondrium. His pain was relieved by strong analgesics and spasmolytics. A few days later he became jaundiced and had melaenas. Daily haemoglobin estimation showed a sharp drop to 48 per cent despite the transfusion of 1200 ml of blood. An emergency barium meal examination ruled out a gastric or duodenal ulcer as a possible source of bleeding. A sinogram revealed a large liver abscess cavity. Melaenas continued and 1250 ml of blood were required to raise his haemoglobin level to 59 per cent. At that time the diagnosis of traumatic haemobilia was established and the decision to operate was made.

At operation on 13 October 1973 the abdomen was opened through an upper midline incision and the common hepatic artery was ligated at its origin. The patient's recovery was smooth and uneventful. The discharge of blood ceased and his haemoglobin increased to 78 per cent. Postoperative investigations of the liver function proved normal apart from a transitory increase of SGOT and SGPT.

Twenty-four days after the ligation of the common hepatic artery and as the patient was about to be discharged, he complained of excruciating pain in the epigastrium. On examination he was in a collapsed state with a rapid and weak pulse and unrecordable blood pressure. It was obvious that he had severe re-bleeding. After resuscitation he underwent reoperation (6 November).

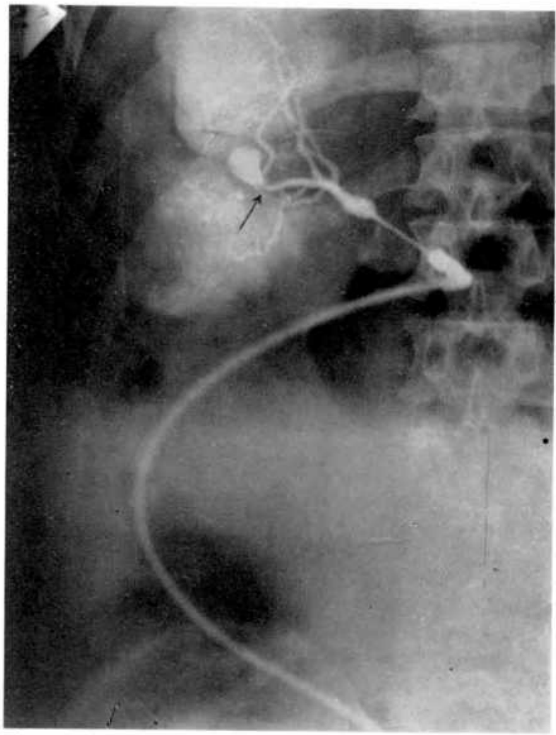

Fig. 1. Right hepatic artery arteriogram. Arrow indicates site of extravasation of opaque medium. This film also demonstrates the fractured ribs and the tube draining the intrahepatic cavity.

The abdomen was opened through the previous incision. The small bowel was full of blood. In order to locate the exact point of bleeding a selective arteriogram was performed by needle puncture through the right hepatic artery (*Fig.* 1). The film taken depicted clearly that the site of bleeding derived from the intrahepatic branch of the right hepatic artery. The right hepatic artery was ligated proximal to the hilus of the liver. His gallbladder and common bile duct were distended by blood clots. Through a cholecystostomy incision the clots of blood were evacuated and a De Pezzer tube was left in position.

The postoperative course was smooth and bleeding stopped. Biochemistry of the liver function was as follows: SGOT 150 u./ml, SGPT 300 u./ml, prothrombin 59 per cent, zinc sulphate test 7·8, alkaline phosphatase 10 KA units.

The patient was discharged on 24 November with his wound completely healed. Three months later re-evaluation of the blood tests gave the following results: haemoglobin 93 per cent, haemocrit 47 per cent, SGOT 65 u./ml SGPT 78 u./ml, alkaline phosphatase 8·9 KA units. The patient's weight had increased by 14 kg to 60 kg.

Table I: SURGICAL PROCEDURES IN TRAUMATIC HAEMOBILIA

1. Lobectomy
2. Ligation of vessels in hepatic cavity
3. Ligation of the common hepatic artery
4. Ligation of branch of the hepatic artery

Discussion

Traumatic haemobilia is a very rare complication of liver trauma. Up to 1968, 31 cases had been reported in the world literature (Wilkinson et al., 1968). Since then we have been able to trace 10 more cases.

The main clinical features of the syndrome are hepatic colicky pain, jaundice and gastro-intestinal bleeding (haematemesis, melaena or both). Undisputable diagnosis can be established by selective arteriography either preoperatively by retrograde catheterization of the hepatic artery or during operation by needle puncture of the same artery. To prevent traumatic haemobilia Turner and Rogers recommended deep sutures for approximation of the traumatized edges of the liver parenchyma. Haemobilia has been reported to occur 2 days to 37 years after hepatic trauma (Caroli, 1959).

Treatment of haemobilia is mainly surgical although conservative treatment has been reported. In *Table I* the various types of operative procedures are listed. Lobectomy has been reported to have a low bleeding recurrence rate although the mortality is increased. Ligation of the bleeding vessels in the hepatic cavity is not always successful and many recurrences have been reported (Wilkinson et al., 1968). Ligation of the common hepatic artery was recommended by Wilkinson et al. (1968). It is a simple procedure, slightly impairing the liver function. Recurrence of bleeding was reported in 3 out of 10 cases. Ligation of the appropriate branch of the hepatic artery should be adequate treatment when the bleeding point has been located by arteriography. Impairment of liver function 3 weeks after ligation of the common hepatic and right hepatic branches was transient in our case.

The high mortality rate with conservative treatment or in undiagnosed cases or in those undergoing irrelevant operative procedures (Manos, 1958; Sandblom, 1972) has been lowered in the past few years as a result of better understanding of the bleeding mechanism and appropriate surgical treatment.

Conclusions

Haemobilia can be diagnosed by the triad of clinical symptoms—colic, jaundice and intestinal bleeding. Preoperative or operative arteriography of the hepatic artery confirms the clinical diagnosis. The treatment is mainly surgical. Of several operative procedures, ligation of the common hepatic artery or ligation of the involved branch has been reported to have a low mortality rate. Bleeding recurs occasionally after common hepatic artery ligation. In our case successive ligation of the common hepatic artery and its right branch has been proved compatible with liver function and survival of the patient.

Gumma of the liver

ROGER PARNIS*

SUMMARY

A misdiagnosed case of gummatous disease of the liver is described.

Case report

An ex-Army clerk, aged 64 years, who had served in North Africa for some time was admitted to St Luke's Hospital, Malta, on 28 March 1974 on account of epigastric pain of 3 days' duration. There were no other recent symptoms and the pain was not related to food intake, but over the previous 6 months there had been a steady loss of appetite and of weight.

In 1959 the patient had had indigestion for a few weeks and 3 years later an antral ulcer had perforated. The perforation was closed and the patient was put on an ulcer regimen. Since then he had not complained of indigestion. He had lived apart from his wife, who had borne him 10 healthy children, for the past 8 years. The cause of the separation, according to him, was loose living on her part. He smoked 20 cigarettes a day but did not touch alcohol.

When examined the patient was seen to be very thin but was otherwise in good shape. His temperature, pulse rate, respiratory rate and blood pressure were normal. He was not anaemic or jaundiced and his fingers were not clubbed. The pupillary reflexes were normal and his tongue was clean. Abdominal examination showed a tender firm liver containing two nodules and extending three fingers' breadth below the costal margin. No other abnormality was detected and CNS examination was negative.

A provisional diagnosis of carcinoma of the stomach with liver metastases was made. Barium meal examination showed narrowing of the antropyloric region of the stomach. A significant amount of barium was retained after 24 hours. The appearances were suggestive of pyloric obstruction which was probably neoplastic in nature.

At operation two swellings were present in the liver, one in each lobe, measuring about 3 cm in diameter. They were firm but not stony hard and were in the substance rather than on the surface of the liver. The liver was not cirrhotic. The site of the old perforation in the antrum was seen, with adherent omentum, but a thorough examination of the stomach revealed no other abnormality. Liver biopsy was carried out and the abdomen closed. The postoperative course was satisfactory apart from a wound infection which caused a small skin breakdown.

Histological examination revealed gummatous fibrosis; there was a fibroblastic reaction with plasma cell and lymphoid cell infiltration and necrosis. Parenchymal tissue was replaced by the fibrosis. No tumour cells were present.

Further questioning and examination of the patient yielded no history or evidence of a chancre or of other manifestations of syphilis. Serological tests were performed:

1. VD reference laboratory test: strongly positive up to 1 : 16.
2. Reiter protein complement fixation test: strongly positive up to 1 : 640.
3. Kahn test: positive up to 0·0125.

A 3-week course of crystalline penicillin, 1 million units 6-hourly, was given with very good results: the liver swelling markedly decreased, the appetite improved and the patient's weight went up. No Jarisch–Herxheimer reaction was noted. He was discharged 4 weeks after admission and was last seen in September 1974 when the liver was not palpable.

Gumma of the liver is today a very rare condition. The predominant symptoms of loss of weight and of appetite plus the presence of an epigastric tumour make a diagnosis of carcinoma of the stomach almost inevitable.

Acknowledgement

I should like to thank Professor G. P. Xuereb for the biopsy examination.

NEW
Praxilene
vasoactivator
INJECTABLE
RELIEVES REST PAIN

NEW

for peripheral vascular disorders

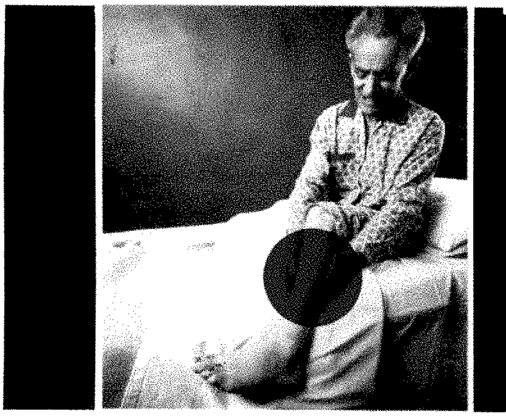
Praxilene

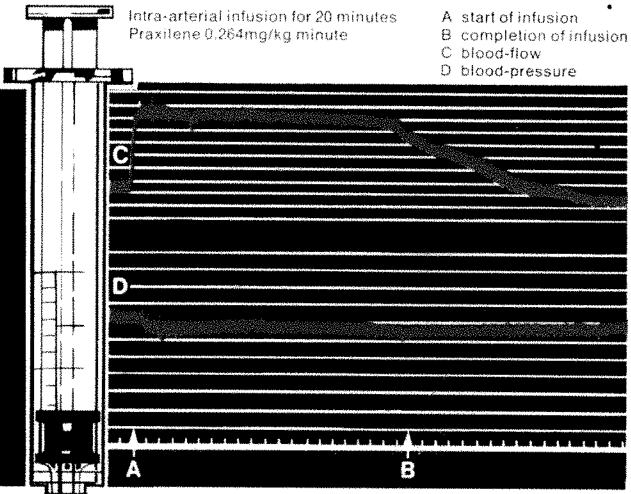
vasoactivator

INJECTABLE

RELIEVES REST PAIN

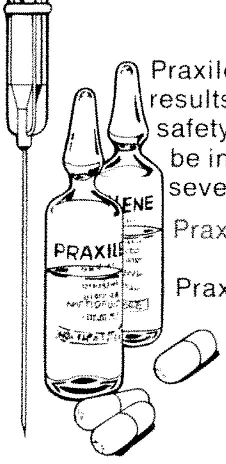
by flushing out pain producing metabolites
by improving blood-flow – without affecting blood-pressure
by a unique metabolic activity





Fast relief
Praxilene administered parenterally (Intra-arterial; Intravenous; Intramuscular) can give relief of pain within as short a time as one week, in many cases.

Prolonged relief
Relief of pain is prolonged: at the same time the collateral circulation is given the opportunity to develop, resulting in an improved blood supply to the affected limb.



Praxilene has produced excellent results because it has a very wide safety margin and the dosage can be individually tailored to the severity of the disorder.

Praxilene: Unique Vasoactivator

Praxilene: Naftidrofuryl: available as 40mg ampoules and 100mg capsules.

Rupture of subcapsular haematoma of the liver in a case of eclampsia

C. H. BROWNE, GILLIAN C. HANSON, L. R. DE JODE AND P. A. ROBERTS*

SUMMARY

A case of rupture of subcapsular haematoma of the liver in a patient suffering from eclampsia is reported in which the patient survived. Peritoneal tap provided important diagnostic information. Surgical intervention with control of the liver haemorrhage provides the only chance of survival.

RUPTURE of a subcapsular haematoma of the liver is a rare complication of pregnancy. There have been 83 previous case reports in the world literature; a further case is reported here.

Case report

Mrs M. H., aged 22 years, had had a normal full term first pregnancy 2 years previously. She had gained little weight during her present pregnancy, which was otherwise proceeding normally. The blood pressure remained normal. At the 32nd week she was admitted as an emergency to Plaistow Maternity Hospital, with slight vaginal blood loss and lower abdominal pain. On examination her pulse rate was 88/minute, and her blood pressure 150/105 mm Hg. The height of the uterine fundus was compatible with the date and the fetal heart was heard. She was sedated with phenobarbitone and started on oral methyldopa. The same afternoon she went into labour; the fetal heart was no longer heard and she produced a stillborn child. The blood pressure at delivery was 180/110 mm Hg. One hour postpartum her blood pressure had risen to 220/110 mm Hg and she complained of epigastric pain. Pethidine and promethazine were given intramuscularly. Four hours postpartum her blood pressure was 170/120 mm Hg, and she had a convulsion lasting 2 minutes. A chlormethiazole infusion was commenced and oxygen given by mask. She had a further convulsion 65 minutes later when the blood pressure was 110/90 mm Hg. Eight hours postpartum she suddenly collapsed and her blood pressure and pulse became unrecordable. Hydrocortisone 400 mg was given intravenously as a bolus and blood transfusion was started. During the next 2 hours she received 8 units of blood and the blood pressure rose to 120/110 mm Hg. She remained pale, with a persistent tachycardia of about 140/minute; the restlessness had decreased and the level of consciousness had improved. She complained of epigastric pain and a sensation of distension in the abdomen. Two hours later her blood pressure and pulse again became unrecordable. She was given a further 2 units of blood and 500 ml of Macrodex 70 and her blood pressure rose to 110/70 mm Hg. The radial pulse was barely palpable.

She was transferred to the Intensive Therapy Unit, Whipps Cross Hospital. On arrival she was pale and sweating; her pulse rate was 120/minute and her blood pressure 100/70 mm Hg. Her abdomen was grossly distended; no bowel sounds were audible. The abdominal distension was thought to be due to ileus related to her shocked condition. On vaginal examination the uterus was contracted and the cervical os closed. A central venous pressure line was set up and the reading recorded as +2 cm water. Despite vigorous intravenous therapy with whole blood and Macrodex 70 her central venous pressure repeatedly fell to zero and she remained severely shocked with cold clammy cyanosed extremities. The level of consciousness had deteriorated and the patient was oliguric. There was a persistent tachycardia of 120–180/minute and the blood pressure fluctuated between 120/110 mm Hg and a low unrecordable level. The abdomen became increasingly distended and 3 hours later shifting dullness was detected. Fresh blood was aspirated on a four-quadrant peritoneal tap. A surgical opinion was sought and an emergency laparotomy arranged.

At operation the peritoneal cavity was distended with blood which was found to be coming from the right lobe of the liver where the capsule had been completely stripped off and ruptured by a subcapsular haematoma. A large subcapsular haematoma was also found over the left lobe. Sheets of Sterispon were applied to the surface of the liver and omentum laid over it. A peritoneal dialysis catheter was positioned in the right iliac fossa.

Postoperatively the patient was transfused with fluid to maintain the central venous pressure at +4–10 cm water; the pulse remained at 120/minute. Her blood pressure was unrecordable for 12 hours and she remained anuric. Peritoneal dialysis was instituted.

Over the next 24 hours the blood pressure rose to 150/120 mm Hg and the dialysate, which was initially heavily blood-stained, began to clear. Intermittent intravenous diazoxide was required for 7 days in order to control the blood pressure. The patient was maintained on intermittent positive pressure ventilation for 10 days. During this time the level of consciousness steadily improved but her seriously ill condition necessitated gradual weaning off the ventilator.

Eleven days after admission a tracheostomy was performed which facilitated respiratory management. The tracheostomy tube was removed 10 days later.

Fourteen days postpartum, because of technical difficulties with peritoneal dialysis and the suspicion that dialysis might have to be continued for some time, haemodialysis was commenced. Seventeen haemodialyses were performed at Whipps Cross Hospital by the Mobile Renal Team. The patient was then transferred to the Renal Unit at the RAF Hospital, Halton, where haemodialysis was continued. She remained oliguric for 5 weeks. She was discharged home 3 weeks later. The creatinine clearance prior to discharge was 23 ml/minute.

Comment

This patient posed a difficult diagnostic problem. At first the collapse appeared to be due either to intrauterine haemorrhage or to septic shock. The former was excluded by vaginal examination and the latter was considered unlikely in the absence of an obvious source of sepsis. In view of the persistent tachycardia in the presence of an initial normal blood pressure (after volume replacement) and an associated decreased level of consciousness, the possibility of an overdose of chlormethiazole was considered.

It is interesting that when the blood pressure rose the pulse volume remained small and the diastolic pressure high; the high diastolic pressure was presumably related to pregnancy toxaemia and gave the misleading impression of a normal dynamic blood volume. It is evident that a diagnostic peritoneal tap should have been performed earlier. After surgery and replacement of the blood volume, the diastolic blood pressure over the next 7 days rose on several occasions to 110–120 mm Hg. This was unlikely to be due to fluid overloading since the central venous pressure remained normal and fluid balance was carefully controlled; it was probably related to postpartum toxaemia.

---

* C. H. Browne, G. C. Hanson and L. R. de Jode: Whipps Cross Hospital, Leytonstone, London. P. A. Roberts: Plaistow Maternity Hospital, Howards Road, London.

In view of the prolonged period of oliguria and the low creatinine clearance 2 months after the onset of renal failure, it is probable that this patient sustained partial renal cortical necrosis.

Discussion

Subcapsular haematoma of the liver and its rupture into the peritoneal cavity have been reported in several countries (Sheehan and Lynch, 1973) since its first description by Abercrombie (1844). Most of the case reports are from Central America, and there are very few from Britain (Roy, 1914; Bellwood, 1915; Links, 1946; Burton-Brown and Shepherd, 1949). Most of the cases were associated with toxaemia of pregnancy and some, as in our case, with eclampsia.

The characteristic hepatic lesion in toxaemia is haemorrhagic necrosis of the periphery of the hepatic lobule, especially of the right lobe. It seems likely that this haemorrhage beneath the liver capsule may extend, causing distension and rupture into the peritoneal cavity. Various factors have been suggested as contributing to the enlargement and rupture of the haematoma; these include slight trauma unrecognized by the patient (Barry and Meagher, 1964), contractions of the diaphragm and abdominal muscles associated with labour (Ayars et al., 1937) and hypertension with vomiting and convulsions (Speert and Tillman, 1952). Ninety-five per cent of hepatic haematomas occur over the anterior or superior surface of the right lobe; this would indicate that the causative factor was blunt trauma against the ribs. In the remaining patients the caudate lobe is involved adjacent to the vertebral column (Touloukian and Ferrer, 1967). In our case, however, the left lobe also contained a large subcapsular haematoma, but which had not ruptured the capsule.

Haematoma formation secondary to disseminated intravascular coagulation has been suggested (Pereyra and Lawler, 1956) as an aetiological factor. In our patient there was no haematological evidence of this.

Our patient complained of epigastric pain immediately postpartum and did not become shocked until after two eclamptic fits during which, presumably, the capsule ruptured.

The clinical picture of upper abdominal pain and gross shock without overt bleeding and in the face of vigorous intravenous replacement therapy should suggest this condition. Abdominal paracentesis provides relevant information for diagnosis (Mokotoff et al., 1967). Urgent laparotomy offers the only chance of survival. At operation various methods of achieving haemostasis have been advocated. These include packing the area with Surgicel (Touloukian and Ferrer, 1967), Sterispon, fat, muscle (Links, 1946) or omentum, suture with catgut on an atraumatic needle (Hakim-Elahi, 1965) and methyl alphacyanoacrylate (Just-Viera et al., 1962). Hepatic lobectomy has not been attempted. Adequate drainage is recommended. In our case the necessity for peritoneal dialysis in the face of acute renal failure enabled us to confirm that bleeding had stopped, as the dialysate became free of blood after 4 days.

The survival rate in operated cases is in the region of 50 per cent. Death usually results from failure to control the bleeding.

Acknowledgements

We thank Mrs R. Selby and Mrs J. Snell for their secretarial assistance, and also the Renal Team from the RAF Hospital, Halton, for their assistance in the management of this case.

Single layer anastomosis after rectosigmoid resection

N. A. MATHESON AND A. D. IRVING*

SUMMARY

Anastomosis after resection of the rectosigmoid colon is often followed by leakage at the suture line. When occult leakage discovered on routine contrast study is included incidence rates of over 50 per cent have recently been reported.

A single layer interrupted seromuscular inverting technique was used for the anastomosis after elective rectosigmoid resection in 52 consecutive patients. The total incidence of suture line leakage was 6 per cent. Therefore a high incidence of anastomotic dehiscence in the rectum can be avoided and it is concluded that a single layer technique is sound.

ANASTOMOSES after rectosigmoid resection appear to be prone to dehiscence, and the more thorough the search the more often is leakage found. In the experience of Goligher, Graham and de Dombal (1970) of 73 patients after anterior resection of the rectum, 40 per cent of anastomoses above the peritoneal reflection and 69 per cent of anastomoses below the peritoneal reflection showed leakage on contrast radiological study with barium about 14 days after operation. In most instances the degree of leakage was minor and not clinically apparent, but 4 of 47 patients after high rectal anastomosis (above the peritoneal reflection) and 7 of 26 after low rectal anastomosis (below the peritoneal reflection) developed either peritonitis or faecal fistula. In a recent comparison of continuous polyglycolic acid sutures with catgut for the all coats layer in two layer anastomoses of colon and colorectum, Clark et al. (1972) found radiological evidence of leakage in 2 of 6 patients after high anterior resection, and in 7 of 9 patients after low anterior resection, an overall incidence of 60 per cent. Of these 9 instances of leakage, 6 were clinically apparent.

For 12 years we have used a single layer of interrupted non-absorbable seromuscular sutures with inversion of mucosa in small bowel anastomosis, and for 6 years the same method has been used routinely in the colon and rectum. Fifty-two consecutive elective colorectal anastomoses made with such a technique were studied with regard to the incidence of leakage. All the patients were examined radiologically with Gastrografin enemas at about 10 days after operation, apart from 1 patient in whom leakage was clinically apparent. Leakage was found in 3 of the 52 patients (6 per cent) and was clinically apparent in 1 of the 3 (2 per cent). These results are an improvement on previously published series and are reported to encourage acceptance of a simple and safe method of anastomosis after rectosigmoid resection.

Patients and methods

During the past 6 years 52 patients have undergone elective resection of the rectosigmoid colon. The conditions requiring operation were carcinoma in 40, diverticular disease in 5 and miscellaneous conditions including stricture, volvulus, villous papilloma and endometriosis in 7. Except in the presence of obstruction, the bowel was mechanically prepared for 4 or 5 days using twice daily colonic lavage supplemented with magnesium sulphate by mouth until there was diarrhoea. During this time phthalylsulphathiazole 4 g daily was given, but other antibiotics were not used.

In the presence of obstruction sufficient to interfere with efficient cleansing of the colon a preliminary transverse colostomy was made, and this was done in 11 patients. A colostomy was made at the time of resection in only 1 patient. Of the 52 operations, the anastomosis was above the peritoneal reflection in 29, at or about the level of the reflection in 8 and below the reflection in 15. Anastomoses at or above the reflection were classified as 'high' and below the reflection as 'low' (Goligher, Graham and de Dombal, 1970); there were therefore 37 high and 15 low anastomoses.

In resection for carcinoma, division of the inferior mesenteric artery and vein was either at the level of the origin of the artery or more usually immediately below the left colic branch. In carcinoma the rectal stump was washed out with 1 : 500 mercuric perchloride and the proximal bowel end was cleansed with a similar solution. Clamps were applied only to the segment of bowel to be resected. The sutures for each operation were made up in anastomosis packets containing 24, 16-mm half circle fine needles threaded with either 40-cm or 75-cm lengths of 2/0 braided nylon (Arbralon, Armour Pharmaceuticals Co. Ltd), depending on the depth of the proposed anastomosis. The posterior layer of seromuscular sutures was inserted parallel to the long axis of the bowel (except for those at each end which were placed first horizontally) at intervals of approximately 5 mm. The proximal bowel was then slid down to the rectal stump and the sutures tied and cut. The anterior layer was made in a similar way, the sutures being tied and cut after the complete series had been inserted.

For many years, if there was pelvic sepsis or obvious faecal contamination at operation, we have washed out the pelvis with 1 litre of saline containing 1 g tetracycline. During the past 2 years this has become routine after colorectal anastomosis.

---

* Department of Surgery, University of Aberdeen and Aberdeen Royal Infirmary.

A drain was used in 26 of the 37 high anastomoses and in all the low anastomoses. The pelvis was not 'reperitonealized'.

The use of neostigmine to reverse the effects of relaxant drugs was avoided since this may contribute to anastomotic dehiscence (Bell and Lewis, 1968) and we are uncertain that giving atropine beforehand completely abolishes the effect of neostigmine on the gut.

All anastomoses were studied radiographically using Gastrografin at or about 10 days after operation, except in 1 patient in whom there was clear clinical evidence of dehiscence.

Table I: SUMMARY OF THE RESULTS

Type of anastomosis	No. of anastomoses	Clinical leak	Radiological leak	Total No.	Total %
High	37	1	1	2	5
Low	15	0	1	1	7
Total	52	1	2	3	6

Results

The results are summarized in *Table I.*

Brief details of the 3 patients in whom anastomotic leakage occurred are given below.

Case 1: A 63-year-old female was operated on electively for carcinoma of the sigmoid colon. There was a fistula between the carcinoma and the jejunum and an extensive associated pelvic abscess, extending to affect the anterior abdominal wall. The carcinoma was resected together with a length of jejunum and the anastomosis was above the peritoneal reflection. A colostomy was not made. There was wound disruption with extensive abdominal wall sepsis early after operation, followed by clinical evidence of leakage at 10 days with a faecal discharge and lower abdominal peritonitis. Re-exploration showed a leak just distal to the anastomosis. The bowel ends were exteriorized, but the patient died of continuing sepsis 1 week later.

This instance of leakage is, strictly speaking, not anastomotic, but the distinction is fine and we feel it right to include the patient as such.

Case 2: A 77-year-old male underwent elective resection for carcinoma of the sigmoid colon. The anastomosis was above the level of the peritoneal reflection. At routine Gastrografin enema examination free leakage of contrast was seen, but this was never clinically apparent.

Case 3: A 74-year-old female underwent elective resection for rectal carcinoma, with the anastomosis well below the level of the peritoneal reflection. Routine Gastrografin enema examination showed free leakage of contrast but this was never clinically apparent.

Of the 3 instances of leakage 1 was gross and clinically apparent, whereas 2 were occult, demonstrable only on the contrast study, and evidently did not interfere with the patient's clinical course. Two leaks (1 gross and 1 occult) occurred in 37 high rectal anastomoses (5 per cent) and 1 occult leak occurred in 15 low anastomoses (7 per cent). Dehiscence was not seen in any of the 11 patients with a preliminary colostomy or in the patient with a simultaneous colostomy.

Discussion

Because of the morbidity and mortality (Goligher, Graham and de Dombal, 1970, Schrock et al., 1973), breakdown of anastomoses in the colon and rectum is a topic of serious surgical concern. Particular attention is focused on the rectum where anastomosis is evidently associated with an incidence of dehiscence in excess of that elsewhere in the intestine.

Conditions affecting the healing of large bowel anastomoses have been reviewed by Hunt and Hawley (1967), Goligher, Graham and de Dombal (1970), Rosenberg et al. (1971), Hawley (1973), Irvin and Goligher (1973) and Schrock et al. (1973). These include general factors such as age, nutritional status, the use of steroids, the nature of the underlying disease and blood loss requiring transfusion.

Efficient bowel preparation (Rosenberg et al., 1971) and the use of an inverting anastomotic technique (Goligher, Morris et al., 1970; McAdams et al., 1970; Irvin and Edwards, 1973) contribute to safety, whereas local sepsis or faecal soiling leads to increased breakdown rates (Letwin et al., 1967; Hawley, 1970; Rosenberg et al., 1971; Debas and Thomson, 1972).

The unwisdom of attempting primary colorectal anastomosis under adverse local conditions is exemplified by the patient in the present series who developed clinically obvious leakage, and additionally by our experience with 2 patients who underwent emergency anterior resection with primary anastomosis during the past 5 years, one a palliative resection in the presence of obstruction with faecal loading and the other resection for perforated diverticular disease with gross pelvic sepsis. Both patients developed clinically obvious leakage and the first died from peritonitis.

A 'protective' colostomy made at the time of resection and anastomosis does not appear to affect the incidence of dehiscence although it may reduce ensuing mortality and morbidity (Goligher, Graham and de Dombal, 1970; Schrock et al., 1973). Such a colostomy was made in only 1 patient in the present series and therefore did not influence the results. However, a preliminary colostomy was made if associated obstruction was thought sufficient to interfere with thorough mechanical preparation, and this was done in 11 patients.

A single layer method of intestinal anastomosis was first advised by Halsted in 1887 and was routinely used by Wilkie (1934). Wangensteen (1945) advocated a single layer technique when he described conservative resection for carcinoma of the rectum, and Gambee et al. (1956), describing results of their experience with single layer techniques over 10 years, reported 163 colonic anastomoses with 11 leaks. The method, however, has never gained orthodoxy in the United Kingdom and Aird's (1957) comment that it requires 'a confidence and courage that most of us lack' may be apt.

Single layer inverting methods have been shown experimentally to be superior to two layer inverting techniques with respect to luminal reduction (Halsted, 1887; Letwin et al., 1967; Orr, 1969; McAdams et al., 1970), tissue strangulation (Letwin et al., 1967; Orr, 1969) and anastomotic strength after the fifth postoperative day (Hamilton, 1967; Letwin et al., 1967; Orr, 1969; McAdams et al., 1970). Histologically, mucosal continuity and muscle realignment occur more rapidly with single layer methods (Orr, 1969; McAdams et al., 1970), and angiographically, healing may be more rapid (Orr, 1969) although this has been disputed (Abramowitz and McAlister, 1969).

There is therefore a great deal of experimental evidence in favour of single layer anastomosis, although not all authors have been able to confirm its superiority in reducing mortality or anastomotic complications (McAdams et al., 1970; Irvin and Edwards, 1973).

The clinical use of single layer methods in rectal anastomosis has seldom been reported, and some American series deliberately exclude this area. A randomized clinical trial (Irvin et al., 1973) comparing single layer with two layer inverting anastomosis in the small and large bowel showed a similar incidence of leakage with each method. Only 7 patients in each group underwent rectal anastomosis, with 2 instances of dehiscence in the two layer group and 1 in the single layer group. A conclusion with specific regard to the rectum cannot therefore be made. A relatively high incidence of dehiscence after single layer anastomosis elsewhere in the intestine is surprising. Whether this is related to the fact that different types of single layer technique were used, that various surgeons were involved and that they were presumably unaccustomed to single layer anastomosis is uncertain but possible.

The reported incidence of leakage in patients undergoing elective resection with conventional two layer colorectal anastomosis and studied radiographically after operation has been 51 per cent (Goligher, Graham and de Dombal, 1970) and 60 per cent (Clark et al., 1972). Further, when the anastomosis was low the incidence of leakage was substantially higher. It is unlikely that either our patients or their management were fundamentally different from those in earlier reports and we are therefore inclined to attribute the low incidence of leakage (6 per cent overall; 7 per cent in low anastomoses) to the single layer anastomotic technique described here. Apart from the safety associated with the use of a single layer technique, there are other advantages of which the most appealing is simplicity. This is especially apparent in very low rectal anastomoses; it is half as difficult to insert one layer of sutures in a deep confined space as it is to insert two. An associated feature is therefore expedience. A less apparent advantage which may nevertheless be significant is that a single layer seromuscular technique avoids mucosal puncture and in theory should be associated with less risk of malignant cell implantation in patients with large bowel carcinoma.

Temporary transcaecal ileal diversion in prevention of anastomotic leak in planned colonic surgery (an alternative to proximal colostomy)

ALAN SIMPSON AND V. K. SRIVASTAVA*

SUMMARY

An alternative to proximal colostomy in planned colonic resection is reported in 30 patients. The physiopathological background for this procedure of temporary transcaecal ileal diversion is explained together with details of the operation and the results obtained.

ANASTOMOTIC leakage after colonic surgery is a hazardous complication, responsible for considerable morbidity and mortality. The immediate success in this field of surgery is almost entirely dictated by the absolute integrity of the anastomosis. At the turn of the century the mortality from this complication alone was between 30 and 50 per cent (Beahrs, 1967).

The recognition of the importance of the influence of leakage from the anastomosis on the immediate morbidity and mortality led to the development of temporary proximal faecal diversion techniques to protect the anastomotic site. These diversions, such as proximal colostomy, caecostomy, etc., have gone a long way towards minimizing the risk of leakage from the anastomosis in colonic resections. However, recent doubt have been cast on the efficacy of such procedures as shown by Irvin and Goligher (1973) and also in our control series.

It appears from the recent literature that not only is the risk of leakage still high (varying from 16 to 51 per cent, the highest incidence being in anterior resections of rectum) but the morbidity and resulting mortality are also appreciable (Herter and Slanetz, 1967; Goligher et al., 1970; Whitaker et al., 1970).

Frequently faced with this problem of colonic anastomosis and appreciating the disadvantages of adding a proximal diversion in planned colonic resections, we considered that the solution lay in finding a diversion technique which could be a part of a one-stage procedure, thereby avoiding the problems associated with the colostomy and its subsequent closure. In our opinion an effective proximal diversion must provide complete physiological and mechanical rest to the anastomosis; this is essential for the healing at the anastomosis to progress unhindered to completion, the anastomosis only regaining its leakproof conducting capacity when healing has been allowed to progress unhindered to completion. In our experience this is not achieved by proximal colostomy (as explained later).

A new technique designed to achieve temporary total proximal diversion has been successfully used in 30 cases of planned colonic resections and is described below.

Patients

The series consisted of 133 planned colonic resections with either colocolic or colorectal anastomosis performed in the West Bromwich Group of Hospitals. One hundred and three cases (control group) were chosen by random selection from cases operated upon by three surgical teams between 1966 and 1974. The remaining 30 patients had the new diversion technique incorporated at the time of resection (1970–4). The control group of 103 cases is compared with these 30 cases for the incidence of anastomotic leakage only.

Methods

Faecal leakage in the present series of cases was evidenced by either the occurrence of faecal peritonitis and/or the appearance of a faecal fistula. Cases with subclinical leakage obviously could not be included.

Clinically, the leakage was divided into major and minor. A major leak meant either faecal peritonitis or persistent faecal fistula. A minor leak included those anastomoses which healed with conservative treatment, without markedly hindering the clinical recovery of the patient.

All the cases including the control series had an intraperitoneal drain to the anastomosis.

Techniques

All the 30 patients had resection of the colon with a two layer anastomosis, the outer layer being interrupted unabsorbable sutures. The technique and level of resection were dictated by the nature and site of the lesion. Unloading of the colon proximal to the resection was ensured as far as possible in every case. After the completion of the resection and anastomosis in the 30 patients, a temporary total ileal-transcaecal diversion was carried out as described below. Appendicectomy was performed and a purse string suture was placed around the base of the appendix site. (If appendicectomy had been performed previously, then a small incision was made in the caecal wall and a similar purse string suture was placed around it.) Via this lumen (appendix base or caecostomy incision) a 22 or 24 French gauge soft Foley-type inflatable catheter was negotiated through the ileocaecal valve into the terminal ileum for a distance of at least

Temporary transcaecal ileal diversion in prevention of anastomotic leak in planned colonic surgery (an alternative to proximal colostomy)

ALAN SIMPSON AND V. K. SRIVASTAVA*

SUMMARY

An alternative to proximal colostomy in planned colonic resection is reported in 30 patients. The physiopathological background for this procedure of temporary transcaecal ileal diversion is explained together with details of the operation and the results obtained.

ANASTOMOTIC leakage after colonic surgery is a hazardous complication, responsible for considerable morbidity and mortality. The immediate success in this field of surgery is almost entirely dictated by the absolute integrity of the anastomosis. At the turn of the century the mortality from this complication alone was between 30 and 50 per cent (Beahrs, 1967).

The recognition of the importance of the influence of leakage from the anastomosis on the immediate morbidity and mortality led to the development of temporary proximal faecal diversion techniques to protect the anastomotic site. These diversions, such as proximal colostomy, caecostomy, etc., have gone a long way towards minimizing the risk of leakage from the anastomosis in colonic resections. However, recent doubt have been cast on the efficacy of such procedures as shown by Irvin and Goligher (1973) and also in our control series.

It appears from the recent literature that not only is the risk of leakage still high (varying from 16 to 51 per cent, the highest incidence being in anterior resections of rectum) but the morbidity and resulting mortality are also appreciable (Herter and Slanetz, 1967; Goligher et al., 1970; Whitaker et al., 1970).

Frequently faced with this problem of colonic anastomosis and appreciating the disadvantages of adding a proximal diversion in planned colonic resections, we considered that the solution lay in finding a diversion technique which could be a part of a one-stage procedure, thereby avoiding the problems associated with the colostomy and its subsequent closure. In our opinion an effective proximal diversion must provide complete physiological and mechanical rest to the anastomosis; this is essential for the healing at the anastomosis to progress unhindered to completion, the anastomosis only regaining its leakproof conducting capacity when healing has been allowed to progress unhindered to completion. In our experience this is not achieved by proximal colostomy (as explained later).

A new technique designed to achieve temporary total proximal diversion has been successfully used in 30 cases of planned colonic resections and is described below.

Patients

The series consisted of 133 planned colonic resections with either colocolic or colorectal anastomosis performed in the West Bromwich Group of Hospitals. One hundred and three cases (control group) were chosen by random selection from cases operated upon by three surgical teams between 1966 and 1974. The remaining 30 patients had the new diversion technique incorporated at the time of resection (1970–4). The control group of 103 cases is compared with these 30 cases for the incidence of anastomotic leakage only.

Methods

Faecal leakage in the present series of cases was evidenced by either the occurrence of faecal peritonitis and/or the appearance of a faecal fistula. Cases with subclinical leakage obviously could not be included.

Clinically, the leakage was divided into major and minor. A major leak meant either faecal peritonitis or persistent faecal fistula. A minor leak included those anastomoses which healed with conservative treatment, without markedly hindering the clinical recovery of the patient.

All the cases including the control series had an intraperitoneal drain to the anastomosis.

Techniques

All the 30 patients had resection of the colon with a two layer anastomosis, the outer layer being interrupted unabsorbable sutures. The technique and level of resection were dictated by the nature and site of the lesion. Unloading of the colon proximal to the resection was ensured as far as possible in every case. After the completion of the resection and anastomosis in the 30 patients, a temporary total ileal-transcaecal diversion was carried out as described below. Appendicectomy was performed and a purse string suture was placed around the base of the appendix site. (If appendicectomy had been performed previously, then a small incision was made in the caecal wall and a similar purse string suture was placed around it.) Via this lumen (appendix base or caecostomy incision) a 22 or 24 French gauge soft Foley-type inflatable catheter was negotiated through the ileocaecal valve into the terminal ileum for a distance of at least

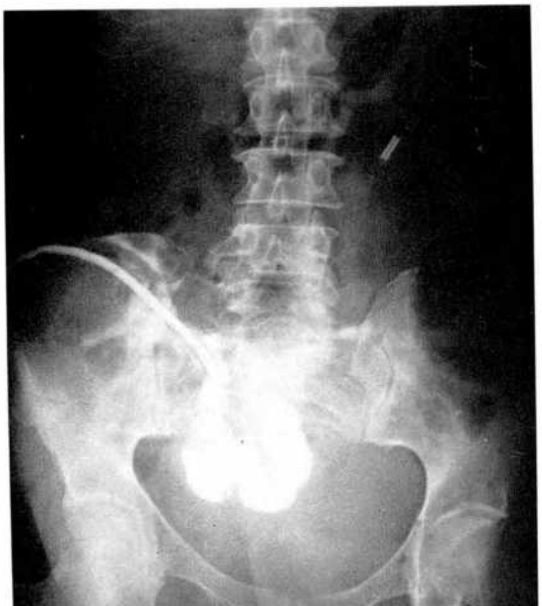

Fig. 2. X-ray film showing the catheter in position and unobstructed flow of contrast media after deflation of the balloon.

15 cm beyond the ileocaecal junction (this tube had been previously brought through an incision in the anterior abdominal wall in the right iliac fossa).

The patency of the lumen and the competence of the balloon of the catheter having been checked beforehand, the balloon was inflated inside the terminal ileum just sufficiently to occlude the lumen of the ileum without causing ischaemia or undue pressure on the ileal wall. The purse string suture around the catheter in the caecal wall was then tightened and the caecostomy site was sutured to the lateral wall of the peritoneum so as to make a leakproof seal between the caecum and anterior abdominal wall.

In some cases of low left colonic resection the anastomosis was also intubated by a rectal tube or large size balloon catheter brought out through the anus; this was left in position for the first 48 hours (*Fig.* 1). Finally, the site of the anastomosis was drained by the use of a corrugated drain.

Postoperative care

In addition to the standard postoperative management particular attention was paid to the following points:

1. Maintenance of patency of the pathway of the catheter into the ileum, this being ensured by occasional injection of 10–15 ml of sterile water or saline (by bladder wash syringe) into the catheter to make sure the channel was clear. This was done once or twice daily as required.
2. A gradual deflation of the balloon of the catheter, beginning on the second postoperative day, was carried out, so that the balloon would be completely deflated by about the sixth or the seventh day; this would allow a gradual flow of the ileal contents into the colon.
3. Careful note of the volume of ileal discharge per day to ensure the catheter bulb was not obstructing the ileum.
4. A radiographic study was done in some cases by injecting Gastrografin into the ileum via the ileal diversion catheter, to see any adverse effect. *Fig.* 2 shows the catheter in position and unobstructed flow of the contrast after partial deflation of the balloon.

Physiopathological basis underlying the operation of temporary transcaecal ileal diversion in colonic resection

The colon is a neuromuscular tube whose main function is to hold and transmit faeces. This is ensured by its reservoir capacity and its ability to carry out controlled segmental and mass peristaltic movements. Any resection (or section) of this neuromuscular tube must interfere with the function of transmission at the point of transection. The restoration of physiological continuity is not immediately obtained by achieving a physical continuity (anastomosis) by means of sutures. Effective leakproof transmitting capabilities are only regained after the natural healing processes have completely sealed the gap. We postulate that in the early stages of healing the anastomotic site presents, to a lesser or greater extent, a ring of obstruction due not to narrowing or physical constriction but to a

However, if the obstruction is due to diverticular disease the ureter should be preserved as recovery is likely after the resection of the diverticular mass. Therefore it is important to make a diagnosis preoperatively, and colonoscopy (Williams and Teague, 1973) together with silicone foam enema (Cook and Margulis, 1961; Hughes, 1969) may be helpful in the difficult case in addition to the routine sigmoidoscopy and barium enema examination. Nevertheless where doubt remains the treatment of a mass of dubious pathology in the sigmoid colon is resection, so that a diagnosis may be established and adequate treatment be performed.

Reviews and notices of books

Progress in Pediatric Surgery. Volume 7
Edited P. P. Rickham, W. Ch. Hecker, and J. Prevot 230×155 mm. Pp. 170. Illustrated. 1974. Munich: Urban & Schwarzenberg. No price given.

THIS is the seventh volume of a new occasional book on paediatric surgery. It is difficult to differentiate it from yet another journal except in its excellent binding. The book contains nine different papers, and only three of these, dealing with reflux oesophagitis, are related to each other. The first paper on stenosis of the oesophagus secondary to hypopharyngeal abscess in the newborn is interesting and reports in detail 5 patients who were all cured. The second paper deals with unusual Siamese twins, the separation attempt leading to the death of both twins. Other papers deal with embryonic sarcomata, congenital duplication of the alimentary tract, obstructive valves of the posterior urethra and primary hepatic tumours in infancy and childhood. All the papers are extremely good and the book is recommended to all those practising paediatric surgery.

H. B. ECKSTEIN

Surgery of the Gastrointestinal Tract
Edited by John S. Najarian, MD, and John P. Delaney, MD. 235×160 mm. Pp. 320+xiv. Illustrated. 1973. New York: Symposium Specialists. $17.50.

IF you like 'reading surgery' in bed, then this is the ideal bedside book. It is composed of about fifty contributions on a multitude of topics, both practical and theoretical, by numerous well-known authorities. They are taken from the proceedings of the Continuation Course on Surgery of the Gastrointestinal Tract organized by the University of Minnesota Department of Surgery. It is impossible to list all the subjects and it would be invidious to mention only some of the authors. Suffice it to say that anyone who operates on the alimentary tract from the oesophagus down will find much of interest. The book is a delightful mix of scientific observation and clinical experience, orthodox and unusual ideas on surgical treatment, surgical technique and experimental studies. All in all, it is an excellent and enjoyable collection of essays by surgeons for surgeons to dip into in a spare moment or even when seeking advice on a difficult clinical problem.

ALAN G. COX.

Mammary Cancer and Neuroendocrine Therapy
Edited Basil A. Stoll, London. 220×160 mm. Pp. 421+xi. Illustrated. 1974. London: The Butterworth Group. £7·50.

To do this book justice would require the reviewer to be as erudite as the editor is in his field. Few can be and this reviewer certainly is not. Nevertheless this book can be recommended strongly, for it brings together a thoroughly confusing and often clinically agonizing subject in a way that provides an up-to-date reference source. It is not, nor does it set out to be, a primer of management for the patient with advanced breast cancer. Rather it is a background of biological information to which the clinician can turn in an endeavour to explain and rationalize the behaviour of his patients. The editor's own contribution is massive and extends also to the text, which is of a high standard and without many of the jerks and humps that characterize multiple authorship.

It is a pity that this symposium, generated, one is glad to see, without the expense of bringing people together, will be rendered out of date so quickly by the advancing tide of facts. Nevertheless, it is a lighthouse for the moment and should be sought out wherever two or three are gathered together trying to help patients with curable and incurable malignancy of the breast.

H. A. F. DUDLEY

Progress in Paediatric Neurosurgery
Edited K. A. Bushe, Göttingen, O. Spoerri, Göttingen, and J. Shaw, Edinburgh. 270×185 mm. Pp. 320, with 268 illustrations. 1974. Stuttgart: Hippokrates Verlag. DM.158.

THIS volume contains the text of 103 papers read at the third European Congress of Paediatric Neurosurgery in September 1972. There has been very little editing, which is doubtless one reason why publication has been possible less than 2 years after the congress. The result is a miscellaneous collection of short papers of uneven quality, many of which, however, will prove of interest to paediatric neurosurgeons, paediatricians, neurologists, neuroradiologists and others who take part in the management of childhood diseases affecting the central nervous system. Almost every reader will find papers of particular importance in his own field of work, especially in the review papers such as those on tumours of the cerebral hemispheres, on intrasellar and suprasellar tumours and on spinal tumours; many of these are by authors who can call upon considerable personal experience.

There are useful collections of papers on subdural effusions and on hydrocephalus with spina bifida aperta. These serve well to remind the reader of the great variation in concepts, methods of treatment and results which are possible in the rapidly developing field of paediatric neurosurgery.

Although the editors clearly did not wish to alter the papers (which range from the concise and formal to the wastefully discursive and conversational style) they should have exercised control of the references. One paper is only a little longer than its references while others contain none at all.

The publishers have clearly found that there is sufficient demand for volumes such as this one which serve to record the proceedings of congresses, but in this age when few of us can keep abreast with the literature in our own subject, a more rigid selection, or, better, publication of worthy papers in the regular journals, should be sufficient. Despite these strictures, these pages contain much valuable information for which neurosurgeons and others will be grateful.

KENNETH TILL

Principles and Practice of Modern Surgery
A. L. Som, Calcutta. Third edition. 245×195 mm. Pp. 172+xii, with 1050 illustrations. 1974. Calcutta: Sadhana Press. No price given.

IT is an indication of its popularity that this is the third edition of a work that first appeared as recently as 1961. In both the second and the present editions the text has been extensively revised. This together with the original production is a tribute to the erudition and the industry of the author.

There are those in Britain who think that much has been lost by the swing away from the teaching of the principles and practice of surgery. The content of this book suggests that its author has no such inhibition. First and foremost, Professor Asita Lal Som is a generalist and his purpose is to inform his readers about surgery; what surgery has to offer, what choice of procedure is available for the relief of many and various conditions and how each operation is carried out, step by step. Pathology and diagnosis are covered and a fair amount of basic surgical and theatre technique is included.

The first eleven chapters are devoted to general pathology; the remaining forty-six to vascular, abdominal, orthopaedic, urological, hormonal, plastic, dental, laryngological, mammary, oesophageal, thoracic and cardiac surgery and to the central and peripheral nervous systems, with, for good measure, sections on dental conditions, the face, head and neck, organ transplantation and reconstructive vascular surgery. There are many illustrations—some ingenious, many good and helpful, a few not so good.

Only dogmatic teaching and a laudable economy of word and phrase have made it possible to put all this between boards. The paper and printing are impeccable. That there are typographical errors is inevitable. That there are some expressions of opinion and even some statements of fact with which the reviewer would disagree is, in such a work, pardonable. Overall, in an age in which undergraduate teaching in Britain has become so academic, it is refreshing to find Asita Lal Som, as he certainly does, 'informing' his students 'about surgery'.

CHARLES WELLS

Machine Diagnosis and Information Retrieval in Medicine in the USSR

Edited A. A. Vischnevskiy, I. I. Artobolevskiy and M. L. Bykhovskiy. 232×150 mm. Pp. 138+viii. Illustrated. 1973. US Department of Health, Education and Welfare. No price given.

THE only excuse for reviewing this book in the BRITISH JOURNAL OF SURGERY is that the surgical decision-making situation has provided the model for some of the most productive studies in diagnostic process. The work of de Dombal's group in Leeds is an outstanding example and has exemplified what this book does not—the need to keep studies of decision-making realistic and in touch with what a clinician is doing day by day. Of course we are looking at a series of papers brought together as a monograph 5 years ago, and furthermore at work which was intended mainly to give a theoretical and mathematical frame against which decision making could be studied. Nevertheless, it is a little disappointing not to see more in the way of results. Those quoted on jaundice are not all that impressive, but doubtless, as in this country and the United States, the later figures are better.

The monograph also illustrates the big gap that still exists between clinicians and mathematicians. A good deal of the jargon and some of the mathematical manipulation is unintelligible unless one is familiar with the work at a research level. It is a pity that those who attack the problem from the analytical end do not spend more time on logical explanation and less on the intricacies of mathematics. What is badly needed is an up-to-date book on new pathways in the analysis of diagnostic process written by a clinician, preferably of course a surgeon. Meanwhile any text is welcome such as this which provides—to paraphrase Henry James—a particular insight from the position in which it stands.

H. A. F. DUDLEY

Instructional Course Lectures. Volume XXII, 1973

The American Academy of Orthopaedic Surgeons. 285×220 mm. Pp. 322+x. Illustrated. 1973. London: Henry Kimpton. £11·20.

THIS volume is a selection of lectures given at the Instructional Courses of the American Academy of Orthopaedic Surgeons; in addition, there is a superb review article on fat embolism by Beck and Collins which could be read with profit by those responsible for the management of major trauma. The clinical aspects, pathology and theories of causation are discussed in detail and there is a critical and stimulating approach to treatment.

Some of the other contributions are almost of the same quality and the editorial committee is to be congratulated on producing one of the best volumes in the series. The article by Connolly and Brooks on vascular problems in orthopaedics is first class; it gives a clear and concise account of the effect of ischaemia on nerve and muscle and emphasizes the importance of fasciotomy in addition to repair of the damaged artery in the management. Swanson describes arthritic disorders of the thumb and the place of flexible implant arthroplasties in the treatment.

The chapter on fractures and dislocations of the hip contains much good advice, which is marred by a recommendation by Lowell that immediate arthroplasty should be considered for bursting fractures of the acetabulum when it is not possible to achieve a stable reduction or a congruous relationship between the femoral head and acetabulum; surely it would be wiser to reserve arthroplasty for patients who are left with appreciable disability.

There is an excellent article by Rhinelander on the effects of medullary nailing on the blood supply of cortical bone. Some of the contributors to this chapter are too liberal with their indications for this technique and readers should digest the section by Brewer on the errors and complications before accepting their advice.

The chapter on Perthes's disease is in places repetitive. The natural history is well described by Fisher; the indications and results of conservative treatment and innominate osteotomy are clearly stated by Gosling and Salter. Urist writes from his extensive experience on the diagnosis and management of osteoporosis and osteomalacia, and there are chapters on the orthopaedic aspects of haemophilia, problems of the forefoot and paediatric osteomyelitis.

The book is well produced and the illustrations are numerous and of good quality. The reviewer read it with interest and profit.

R. BARNES

Accident Surgery and Orthopaedics for Students

J. R. Pearson, Birmingham, and R. T. Austin, Leicester. 248×184 mm. Pp. 218+xiv. 1973. London: Lloyd-Luke (Medical Books) Ltd. £2·75.

THE declared purpose of the authors of this book was to produce a single volume text dealing with orthopaedics and accident surgery in a concise, practical but informative manner for medical students. They have succeeded in their intention by producing a valuable aid and guide not only for medical students but also for junior staff working in accident and emergency departments. The layout of the book has been well considered in regard to easy reference, which is important to those for whom it is designed. Inevitably, there must be some personal criticisms about emphasis, but, bearing in mind the object of the book, these are few and the text is generally well balanced. The opportunity of condemning the use of equine anti-tetanic serum as a means of achieving specific immunity if there is a special risk might have been taken in view of the increasing availability of human tetanus immunoglobulin.

This book does not cover all the problems encountered in accident and emergency departments, but it provides a valuable and appropriate contribution to the areas of accidents and orthopaedics. It can be recommended not only to individuals but also for inclusion in departmental libraries. The price is certainly reasonable.

DAVID M. PROCTOR

The Cervical Spine

Robert Wayne Bailey, Detroit, Michigan. 260×185 mm. Pp. 263+viii. Illustrated. 1974. London: Henry Kimpton. £9·50.

THE cervical spine is a region with such a variety of interesting, varied and challenging pathological conditions that it is surprising that previously there has been no book devoted to this subject. To quote his own words, the author has intended the book as 'a complete and informative text on the cervical spine'. There are chapters on embryology, anatomy, congenital abnormalities, injuries, degenerative diseases, infections and tumours, to name just a few.

It is with reluctance that one must state that this book has not fulfilled the author's intention. There are some excellent chapters such as those on dynamic anatomy and cine-radiography, congenital deformities and infections. However, the sections dealing with injuries are incomplete in description, classification and treatment. A student would have difficulty in obtaining guidance on the treatment of a specific fracture. Cervical spine degeneration is better described in current journals; clinical anecdotes replace a more detailed study of the subject.

The illustrations are radiographs to a large extent. Many of these are of poor quality. Some are so bad that the normal anatomy cannot be seen, let alone the pathological changes.

It is regrettable that the poor sections of this book may prevent the reading of the better chapters.

E. L. TRICKEY

Reviews and notices of books

Pathology of the Cardiomyopathies

Brian McKinney, London. 224×150 mm. Pp. 594+xii. Illustrated. 1974. London: The Butterworth Group. £12·75.

It has been a pleasure to study this splendid book by Dr McKinney, who presents a comprehensive account of the clinical and anatomical pathology of the cardiomyopathies—those diseases of the heart not directly due to lesions of the coronary arteries or valves, or to systemic hypertension or congenital cardiovascular malformations. He has read extensively and brought together into one handy volume information widely scattered in the world literature to supplement his own long experience in this difficult field, dating from his early work in Africa. The reviewer found the sections on tropical and animal cardiomyopathies particularly valuable, for these have been a special interest of the author, but there are reliable accounts, with full bibliographies, of almost every condition which the pathologist (and clinician) must consider in the clinicopathological investigation of mysterious heart failure, and at the last 'court of appeal', as it were, in fatal cases.

The account is in two main parts. The first, shorter section deals with 'primary' cardiomyopathies, and the second, longer one with 'secondary' cardiomyopathies. As with most suggested classifications, the dividing line between primary and secondary types is blurred, and several of the author's primary types (e.g. Refsum's syndrome, oxalosis, Friedreich's ataxia) really belong to the secondary group by his own definitions; however, this is an unimportant detail.

The illustrations are good, and printer's errors commendably few and trivial (apart from the reference to Refsum's syndrome on p. 83). Heading 'strengths' are in places inconsistent and a little confusing, but this can be remedied easily in the next edition. The price seems high but not excessive considering that specialist book costs have more than doubled in the past 10 years.

Dr McKinney's many friends are delighted that he has been able to bring his work to fruition. Despite obstacles which would have daunted those of lesser courage, he has written a book of great value which will find a worthy place in all departments of pathology and cardiology. Congratulations.

REGINALD E. B. HUDSON

Surgery of the Lung. The Coventry Conference

Edited R. E. Smith, Warwickshire, and W. G. Williams, Coventry. 222×145 mm. Pp. 276+xiv. Illustrated. 1974. London: The Butterworth Group. £6·50.

The postgraduate conference held in Coventry in 1973 on lung surgery is a sequel to a previous conference held in that centre on oesophageal surgery. The success of the conferences is reflected in this well-produced publication.

The subjects presented range from the assessment, treatment and results of surgery for bronchogenic carcinoma to clinical lung transplantation. All the discussions are reported.

Surprising variation in the criteria of operability of carcinoma of the lung still exists. Mediastinoscopy clearly is a useful method of assessing operability, but again appears to be very 'operator'-dependent. The technique has reduced the incidence of failed thoracotomies for carcinoma of the lung.

Techniques in the surgery of the trachea are well reported by Dr Pearson of Toronto. Benign strictures of the trachea following long term ventilatory support have provided a large experience in North America, compared with that seen in the United Kingdom.

The methods of bronchoplastic repair, in particular sleeve resection of the lung, are well covered. This is particularly appropriate, since this technique was first performed and pioneered in England by Price-Thomas in 1947.

Clinical lung transplantation is not attended with the success accorded to the kidney or the heart. The technical, pathophysiological and immunological work described is impressive. The degree of failure in the experimental field is still high, although much of the work is carried out in dogs and this may be a species-dependent phenomenon. Up to the present time there have been no long term survivors—long term = greater than 1 year—following human lung transplantation, and of the short term survivors, one lived for 9 months, the majority not living for more than 2 months.

The contributors to this conference are all leaders in their respective area, and therefore the book presents an up-to-date compendium of current practice in surgery of the lung, trachea and major bronchi.

CHRISTOPHER LINCOLN

Book notices

[The Editorial Committee acknowledge with thanks the receipt of the following volumes. A selection will be made from these for review, precedence being given to new books and to those having the greatest interest to our readers.]

Orthopedie Traumatologie 1972
S. Baux, J. Bedouelle, M. Bombart, J. Desbrosses, J. Lagrange, P. Masse, J. P. Razemon, and J. Vidal. 175×225 mm. Pp. 176, with 111 illustrations. 1974. Paris: L'Expansion scientifique français. 65F.

Chirurgie der Gegenwart. Number 5, Volumes 2 and 4
Edited Rudolf Zenker, München, Franz Deucher, Aarau, and Wilhelm Schink, Klön. 260×180 mm. Pp. 42+96. Illustrated. 1973. München: Urban & Schwarzenberg. No price given.

Foot Disorders, Medical and Surgical Management
Nicholas J. Giannestras, Cincinnati, Ohio. Second edition. 260×184 mm. Pp. 669+xii. illustrated. 1973. London: Henry Kimpton. £16·85.

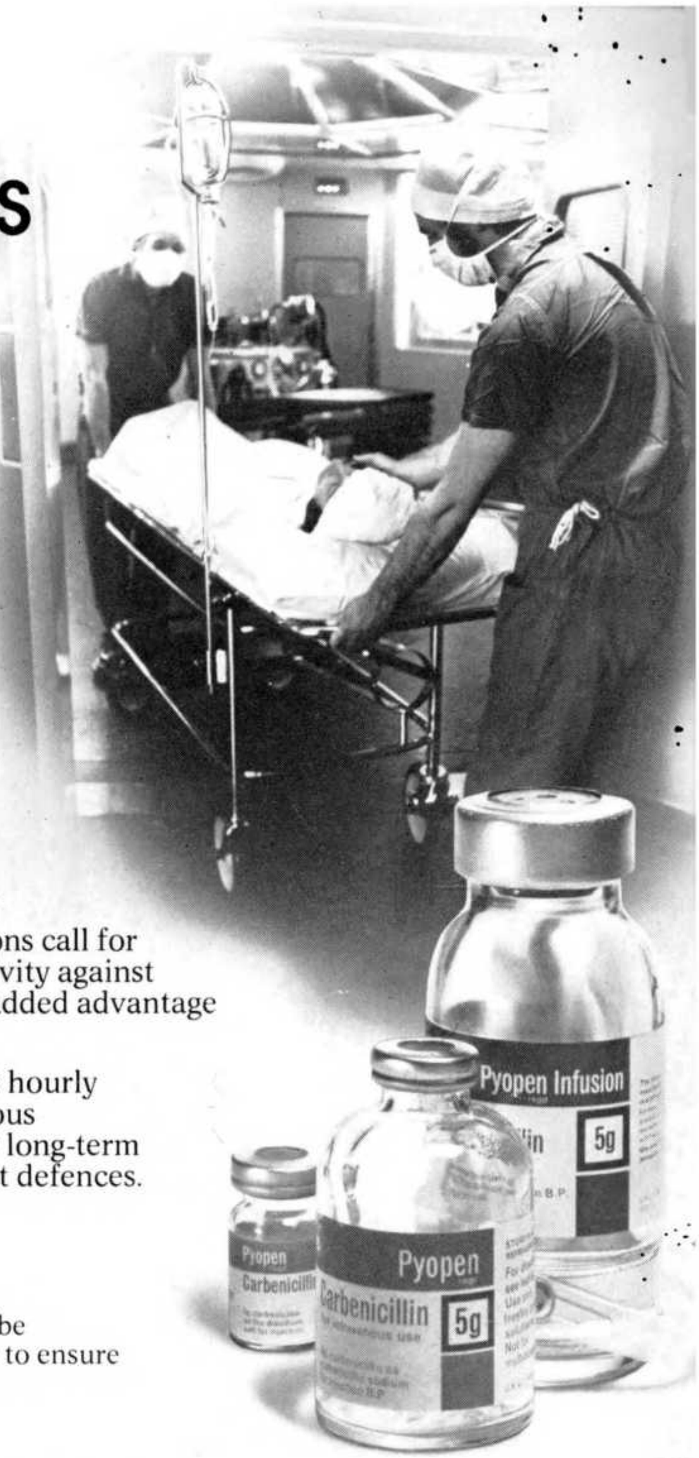
Multivariate Analysis and Psychological Theory
Edited Joseph R. Royce, Canada. 235×160 mm. Pp. 567+xvi. Illustrated. 1973. London: Academic Press Inc. £8·20.

Current Practice of Biliary Surgery
Gabriel A. Kune, Melbourne. 241×165 mm. Pp. 419+xxii. Illustrated. 1972. Edinburgh: Churchill Livingstone. £8.

The Influences of Pancreatic Tumours on the Stomach
Robert M. Zollinger and David W. Coleman, Ohio. 235×160 mm. Pp. 205+xiii, with 83 illustrations. 1974. Springfield, Ill.: Charles C. Thomas. No price given.

Isolated Organ Perfusion
Edited H. D. Ritchie, London, and J. D. Hardcastle, Newcastle. 222×140 mm. Pp. 214, illustrated. 1973. London: Crosby Lockwood Staples, Granada Publishing. £5·75.

When pseudomonas threatens...



Pyopen

The skill of the surgical team,
hours in the theatre, the most advanced
techniques in the world . . . and infection
can still throw the outcome into jeopardy.

Systemic pseudomonas or proteus infections call for Pyopen. Only Pyopen offers you good activity against these Gram-negative organisms with the added advantage of penicillin safety.

Intravenous Pyopen, at a dosage of 5g 4–6 hourly will rapidly control many of these dangerous infections. And Pyopen is also suitable for long-term therapy and for patients with lowered host defences.

Adult Dosage
5g I.V. 4–6 hourly.
In patients with renal impairment dosage may be reduced; monitoring is advisable in these cases to ensure adequate serum antibiotic levels.
Contra-indication
Penicillin hypersensitivity.
Side-effects
As with other injectable penicillins. In rare cases, skin and mucous membrane haemorrhages due to interference with normal clotting mechanisms have been reported.

Pyopen–by infusion or injection

Biochemical Values in Clinical Medicine

5th Edition

R. D. EASTHAM, MD, MRCP, FRCPath, DCP, Dipl Path, *Consultant Pathologist to the Frenchay Group of Hospitals, Bristol*

This book provides an accurate summary of the ways in which various conditions affect many biochemical tests, in each case giving the normal values and a commentary on the interpretation of results attained. Knowledge of the significance of abnormal results of biochemical tests continues to expand and this fifth edition has been extensively revised with the inclusion of some thirty new sections, including various auto-immune antibody tests, polypeptide hormone estimations, therapeutic drug levels and notes on the value of amniocentesis in antenatal biochemical detection of inherited disease and on interlaboratory results of various tests. This quick-reference pocket book will continue to be invaluable.

ACM endoscopes leave nothing to the imagination

st surgeons today recognise the superiority of endoscopy as a ans of confirming diagnoses of colon diseases. It can be quicker d easier than laparotomy, and is also less traumatic for patients and kes fewer demands on hospital facilities.

The premier instrument for colonic investigations is the ACM F9L oscope. Advanced features include 12X magnification and a sharp, de angle circular image three times larger than competitive trument's.

With it a surgeon can clearly view as far as the caecum, take biopsy ecimens and perform polypectomies. After surprisingly little actice, colоscopy can be most rewarding. And the ACM coloscope exceptionally easy to use – a single, one-handed joystick controls e poly-directional tip.

There's a shorter version, too, the F9S which will reach to the nsverse colon and beyond. For the experienced coloscopist there's the dual channel F9A, a major operative, as well as diagnostic instrument.

To find out more, please use the coupon. Or write or telephone.

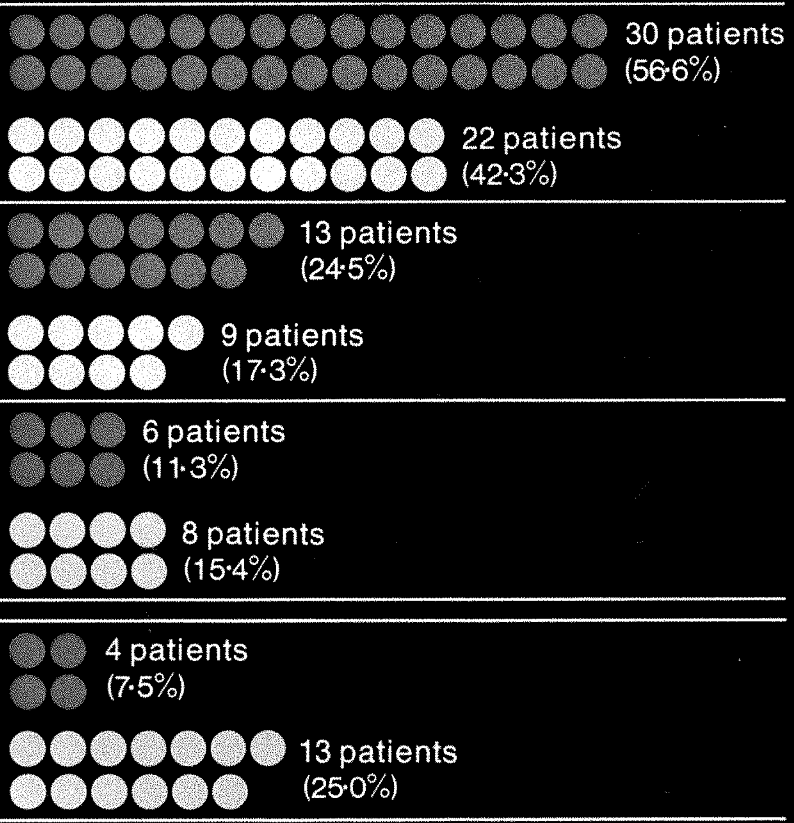
The new evidence for Trasylol in the treatment of acute pancreatitis

Prospective double-blind trial in 105 patients over a five year period shows Trasylol to significantly reduce mortality and morbidity in acute pancreatitis.[1]



Course of illness	
Mild	30 patients (56·6%) 22 patients (42·3%)
moderate	13 patients (24·5%) 9 patients (17·3%)
severe	6 patients (11·3%) 8 patients (15·4%)
DIED	4 patients (7·5%) 13 patients (25·0%)

● Trasylol group (53)
○ placebo group (52)

'Trasylol must therefore be regarded as a drug which is beneficial in the treatment of acute pancreatitis.'[1]

Nouveau traité de technique chirurgicale
New treatise on surgical technique
Volume XV: Urology

by R. Couvelaire and J. Cukier
published under the direction of
J. Patel and L. Leger

This superbly illustrated volume is consecrated to the surgery of the urinary apparatus (kidneys, ureters, vesica, urethra) and the male genital apparatus (testicles, epididymis, spermatic ducts, prostate). The authors carefully signal foreseeable difficulties and, whenever appropriate, analyse the indications and counter-indications for a given mode of action. An authoritative guide to the principles and particularities of each operation.

Text in French. ISBN 2-225-39358-3. 848 pp., 993 fig., 335 francs (in January 1975).

EDITORIAL NOTICES

Original articles or reviews are invited and editorial communications should be addressed to the *Editorial Secretary, British Journal of Surgery, c/o John Wright & Sons Ltd., Bristol BS8 1EX.* Articles are accepted on the understanding that they are contributed to this Journal only, and that articles and their illustrations become the property of the Journal unless the authors state, before publication, that they reserve the right to themselves. Each article should be accompanied by an adequate summary, suitable for publication. Authors are asked to ensure that original illustrations are securely packed and adequately protected.

BUSINESS COMMUNICATIONS should be addressed to *John Wright & Sons Ltd., British Journal of Surgery, Bristol BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery.*

BINDING.—Handsome Cloth Cases may be obtained for binding Vol. 60. Case, £2·00 post free; Case and binding, £7·50 post free. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers, who will also undertake the binding if desired.

ADVERTISEMENTS.—All communications should be addressed to *Hexagon Publishing Co. Ltd., 10 Spencer Street, St Albans, Herts AL3 5EG* (telephone St Albans 60641).

Instructions to Authors

PREPARATION OF MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

ILLUSTRATIONS AND TABLES

Illustrations should be clearly marked on their backs to show number, orientation and author's name. Explanatory legends should be typed on a separate sheet of paper accompanying the manuscript. For halftones, glossy photographs or positive prints (*not* X-ray negatives or slides) should be sent, unmounted wherever possible. When coloured illustrations are submitted as colour prints, they should be accompanied by the original transparencies where possible. As colour illustrations are expensive to reproduce, authors may be asked to make a contribution towards the cost. Drawings should be in a finished state suitable for reproduction. Any lettering should be large enough to withstand a reduction in size; sans serif lettering is recommended.

Tables should be typed on separate sheets of paper accompanying the manuscript. They should have an identifying number and a short descriptive heading. *All illustrations and tables must be referred to in the text.*

REFERENCES

The citation of references should follow the pattern shown in the Reference Citation Recommendations issued by the Medical Section of the Library Association. Copies of these recommendations can be obtained from the Secretary, Medical Section, The Library Association, 7 Ridgmount Street, London WC1E 7AE.

The name of the author and the date of publication are given in the text; the list of works cited is put at the end of the article, arranged in alphabetical order of authors' names. When references to two or more works by the same author are listed, they are arranged in chronological order. Where there are two or more authors (apart from the main author), these may be indicated in the text citation by the words 'et al.', following the name of the principal author; on the rare occasions when this may lead to confusion, the text citation should name as many of the collaborating authors as are necessary to identify the work cited. When several works published by the same author(s) in the same year are cited, they should be distinguished by the letters a, b, c, etc., placed immediately after the date.

In the list of works cited each reference to a *journal article* should give, in the order indicated, the names and initials of all authors, the year of publication (in parentheses), the title of the paper, the name of the journal (abbreviated), the volume number (in heavy type arabic numerals) and the numbers of the first and last pages of the article. Abbreviations for journal titles should be those adopted by *Index Medicus* since January 1971; where no abbreviation is given by *Index Medicus* the journal title should be left in full and the publishers will provide a suitable abbreviation. A reference to a *book* should give, in order, the names and initials of all authors, compilers or editors, the date of publication (in parentheses), the title of the book, the edition number (if other than first), the place of publication, the publisher's name and, where appropriate, the number(s) of the page(s) referred to. A reference to a *contribution to a book* should give, in order, the names and initials of all authors of the contribution, the date of publication (in parentheses) and the title

of the contribution; then, after the word 'In:', there should follow the name(s) and initial(s) of the author(s) etc. of the book, the title of the book, the edition number (if other than first), the place of publication, the publisher's name and the numbers of the first and last pages of the contribution.

Titles of papers and books should be given in the original language, with titles in Cyrillic and Greek alphabets transliterated

Only in papers in which many and frequent references have to be made should the items be numbered; the numbers may then be inserted in the text without interrupting it with a list of names and dates.

IMPERIAL CANCER RESEARCH FUND

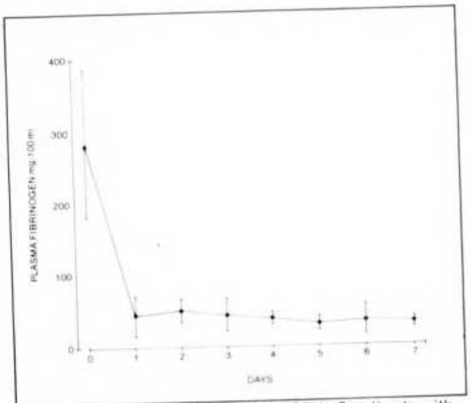
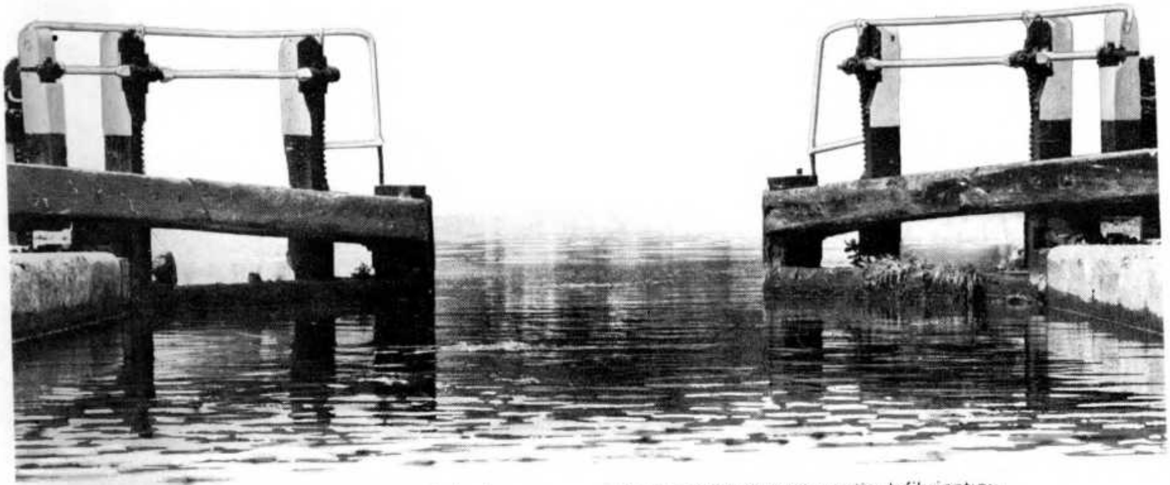
A unique drug is now available to the specialist for routine anticoagulant therapy, and to the researcher as an aid to the elucidation of thromboembolic disorders. Its name is Arvin.

Arvin reduces plasma fibrinogen to a level that maintains marked hypocoagulability without serious spontaneous bleeding complications. This desirable effect is achieved through the specificity of Arvin for fibrinogen—other clotting factors are unaffected.

This state of 'pure' defibrination has an important clinical place when prophylactic measures need to be taken in occlusive vascular disease. e.g. to prevent the formation and extension of thrombi and the dissemination of emboli.



Mean plasma fibrinogen level ± SD in 9 patients with venous thromboses. Arvin 2 units/kg body weight intravenously every 12 hours. From Pitney WR, (1971). Thromb Diath Haemorrh, *45*, 43.



Consistent features of Arvin therapy include an absence of thromboembolic events during treatment, absence of fibrinogen rebound and low incidence of rethrombosis after treatment has ceased. On withdrawal, plasma fibrinogen returns to haemostatic levels within 12 hours and to normal after 10-20 days. Thus, the changeover to oral anticoagulants is smooth and complication-free.

A consistent dose-effect relationship which ensures simple and precise control methods has been established for Arvin. On this basis, we can recommend this drug for a range of indications where controlled therapeutic defibrination is desirable.

For instance, deep vein thromboses, central retinal and branch vein thrombosis, priapism, pulmonary hypertension of embolic origin, embolism after prosthetic cardiac surgery and rethrombosis after thrombolytic therapy have been shown in clinical trials to respond well to Arvin.

To find out more about the unique Arvin concept specialists are invited to write to us for detailed clinical literature and prescribing information.

Nolvadex-a more acceptable approach to breast cancer treatment

Drug therapy is often both uncomfortable and distressing for the patient with advanced breast cancer. But now a more acceptable treatment is available for such patients, 'Nolvadex' (tamoxifen).

'Nolvadex' is an oestrogen antagonist. Whilst it is just as effective as other treatments, it has no hormonal properties. Virilization–common with androgens–is unknown; oedema, nausea and vomiting occur much less frequently than with oestrogens.

'Nolvadex' is taken as twice-daily oral doses. So treatment is simple as well as more acceptable.

Further information–including the results of U.K. trials with 'Nolvadex'[1,2] is available on request.

The importance of environmental conditions, especially temperature, in the operating room and intensive care ward

LORD BROCK*

SUMMARY

Although most patients are essentially well enough to be able to resist or to adapt to unfavourable ambient conditions, this may not be so with an ill patient or one who is having or has had a serious operation. The climatic conditions necessary in the operating room to give an optimal environment are discussed. These are second in importance only to control of infectivity. Air-conditioning in operating suites should be obligatory; there is even official acceptance of this. Earlier recommendations that the operating room should be heated to up to 80 °F (27·9 °C) are obsolete. The temperature most favoured by surgeons is 18·5–21 °C; some prefer a range of 21–22 °C. The critical ambient temperature desirable is 21 °C. For infants and children this may be increased up to 24 °C. It is difficult or impossible to achieve climatic conditions in the operating room that are acceptable to all. The needs of the patient are of special importance and are largely neglected; he alone is unable to speak for himself. The disposition of air inlets in the operating room is fully discussed.

Climatic conditions in the intensive care unit are of great importance and are discussed. The need for full air-conditioning is absolute although this is often ignored. The delivery of conditioned air within the intensive care unit is also fully presented, especially the need to avoid direct chilling of the patient. The advantages of horizontal laminar air flow are presented.

THE importance of a study of central and peripheral temperatures in the recognition of hypovolaemia after open heart surgery was presented in the report of a case (Spitzer and Brock, 1968). A later article (Ross et al., 1969) on observations of central and peripheral body temperatures in the understanding and management of shock dealt with the valuable information that can be obtained essentially in regard to hypovolaemia as a major cause of shock. This work was based on the report of Ibsen (1967) on this subject.

Prolonged experience with the study of central and peripheral temperatures and of the gradient between them has served to reinforce the statement (Ross et al., 1969): 'we now feel unable to manage the care of a patient potentially or acutely ill without having information that temperature studies give'. It still remains true that 'few people are aware of such studies and we have even been told that all the information we are presenting is available by a simple touch of the hand on the nose or the feet of the patient.' Far from this information being of little value the present author remains convinced that much can be learned from it.

Most patients are essentially well enough to be able to resist or to adapt satisfactorily to unfavourable conditions so that these often do not matter greatly. It is different with an ill patient or with one who is having or has had a serious operation.

Let us first consider the significance of the climatic conditions in the operating room to which the patient and members of the operating team are exposed. Much has been written about this in recent years but the extent to which practical measures have been taken to achieve an optimal or even improved environment has varied considerably. It is important that the fullest consideration should be given to all the problems involved in view of the very large sums of money that are being spent on hospital construction and that will affect the comfort and recovery of patients and also the life and work of doctors, nurses and of many others for decades or even generations to come.

Amongst the many publications on these matters attention is drawn to the Report of a Committee of the Royal College of Surgeons (1964) on 'design of operating theatre suites'. The most important factors relevant to the design of operating suites are those concerned with the avoidance or minimization of infection; clearly these are paramount. The transition from the old operating theatre through antiseptic to aseptic conditions was a brilliant and revolutionary achievement. Next in importance is the provision of

---

* Department of Surgical Sciences, Royal College of Surgeons, London.

suitable climatic conditions for all those within the operating suite, including the patient.

It used to be taught that it was in the patient's interest for the temperature in the operating room to be between 70 and 80 °F. One well known and popular textbook of surgery states 'The theatre . . . must be equipped with a heating system capable of maintaining a temperature of up to 80 °F.' That is 27 °C!

Without air-conditioning the operating room can be uncomfortable and conditions may become intolerable. Operating room temperatures during the summer in the city of New York have reached the high 90's with associated high humidity and consequent hyperpyrexia developing (Clark and Ravenstine, 1954). Such conditions are almost obsolete in the USA now that air-conditioning is used. In Great Britain the need for air-conditioning in operating suites is by no means generally accepted (Ministry of Health, 1967). Happily, reason is prevailing and there is wide, even official, acceptance of the absolute need for full air-conditioning in most operating rooms (Medical Research Council and Department of Health, 1972). It is necessary to emphasize that air-conditioning must include control of temperature and humidity and does not mean just forced ventilation.

Two other comments are appropriate at this point. The first is relative to the post-anaesthetic recovery area (that surely must be treated exactly as the operating room) and to the intensive care unit.

The introduction of the intensive care unit is one of the most important and profound changes that has been seen in the clinical lifetime of most of us. Much of the organization of the intensive care unit is concerned with the measurement of parameters that give exact information about vital phenomena instead of relying on the observations and judgements of 'good nursing'. The improvements in care that result are immense, as we understand more exactly and more deeply what is going wrong with the patient and what therapeutic adjustments are needed. However, the general neglect of deliberate consideration of the environmental conditions of the patient in the intensive care unit is surprising. For example, a recent authoritative article on 'surgical intensive care' (Walker, 1973) discusses thoroughly the various parameters that must be measured but makes no mention at all of the environmental conditions that may be important causes of undue extra stress.

In a recently published special brochure devoted to intensive care *Health and Social Service Journal*, 1974) seventeen intensive care units are described and in only two is air-conditioning mentioned as being included in the primary design; in one other it was excluded on grounds of economy and later had to be added. In none of the other fourteen is it even mentioned. It is refreshing to read in an article on the organization and design of intensive care units (Verner, 1974) 'Air-conditioning is essential in intensive care units.'

In the present author's opinion the value of the various parameters can be greatly increased by ensuring that the patient is exposed to a standard controlled environment that shields him from unfavourable ambient influences. The improvements in physiological observation and care that are so important among the aims of the intensive care unit should surely be extended to physical environment. It should be axiomatic that in planning the intensive care unit in every new hospital building provision should be made for full air-conditioning. When such a department is to be set up in an existing hospital it must necessarily be fashioned around or within existing accommodation and therefore shares the climatic disadvantages that the original wards or rooms may possess—disadvantages that may not be important in the original use of the quarters but may become extremely so in their new use.

Experience reveals examples of this, especially in regard to the weather aspect. The main outlook may be south or south-west and this can lead to intolerable conditions at certain times of the day and during some seasons of the year. Conversely, an eastern or northern aspect can produce adverse conditions at the other extreme, particularly if the wind is in an unfavourable direction. An intensive care area often has a mixture of aspects of varying types but which have the one common factor that at certain times, either of the day or of the night, they each produce or contribute to an unfavourable environment for the patient. Much can be done to mitigate this in simple ways, such as by double glazing or efficient shading; proper care should always be directed to what are often obvious and simple measures to be taken but which are just not considered or are ignored. However, the basic essential requirement is full air-conditioning.

The second comment that is inseparable from the issue arises directly from this, namely the type and design of air-conditioning to be used. The usual attitude to air-conditioning is that it is an entity like the provision of gas, water and electricity and can be requested and installed as such. This seems to be the conception of most surgeons, doctors or administrators when faced with the problem of the design of a new building or the conversion of an old one. The need to discuss with the engineers the type of air-conditioning to be installed so as to secure the best conditions is far too little appreciated. Inevitably the engineer, in most instances, is likewise unlikely to be aware of just what is required. He will have full knowledge of the basic facts of ventilation, of control of temperature, humidity and filtration etc., that he can put at the disposal of his clients but he must or should be carefully informed of exactly what is required. The installation of the plant, the trunking and the outlets will be complex and expensive and will require conformity to or alteration of building design to accommodate them. The installation will inevitably be there for many years whether it is the right arrangement or not. Close cooperation between the doctors and the engineers is essential to ensure that it is known exactly what is needed.

As the author is not an engineer the following suggestions may be incorrect, incomplete or impractical but it is hoped they will serve as a basis for discussion. The suggestions now made are not meant to be complete or final or even fully reasoned. My team is embarking on a series of observations to try to introduce method to certain recommendations or suggestions. The securing of relevant information is time-consuming and is not easy. It is hoped to report in later articles on progress on various aspects of the problems that exist as information is gained.

The basic design and function of the central plant and equipment must be the responsibility of the heating and ventilating engineers. The author is chiefly concerned with the mode of delivery of the conditioned air to the operating suite or to the intensive care unit and hence to the patient.

Let us take the operating room first; apart from the anaesthetic room the requirements of the other rooms follow almost inevitably with the essential provision that the area of highest air pressure will be the operating room and the aseptic area in general, and the arrangement of doors, windows and other features will be such as to encourage the desired scheme of air circulation or air flow. While recognizing the prime need for attaining the highest standards of asepsis, of really clean air and the avoidance of contamination from any source, space does not permit a full consideration of these; in any case much has already been written about the control of infectivity. For example, environmental surveys of the operating suites at various RAF hospitals have been well reported by the Royal Air Force Institute of Health and Medical Training (1972a, b) at Halton under the overall direction of Group Captain I. A. McIntosh; a very high standard of infectivity control is achieved with consequent lessening of the incidence of postoperative infection. The present remarks will be confined essentially to the climatic factors involved.

Mention has already been made of the modern readjustment of views on the temperature ranges desirable in the operating room and that the earlier recommendation of up to 80 °F (27 °C) is unacceptable. It should be realized, however, that it is not possible to provide the temperature conditions to suit the needs of all those working in the operating room. The surgeon, the anaesthetist, the scrub nurse, the other nursing assistants and the ancillary workers may all require different conditions. This has been well shown by the work of Wyon et al. (1968) on thermal comfort during surgical operations.

The individual who is in danger of being overlooked is the *patient* and he, of course, is the one being who is unaware of and unable to take protective action if the climate to which he is exposed is uncomfortable, undesirable or even dangerous.

It is important to recognize this difficulty or impossibility of achieving climatic conditions in the operating room that are acceptable to all. Wyon et al. (1968) found that most surgeons preferred temperatures around 66·5 °F (19 °C) at 50 per cent relative humidity and 25 ft/minute air movement, allowing for the average amount of thermal radiation from the operating room lamp. At this temperature nearly half the anaesthetists would feel too cold; they mostly preferred temperatures around 71 °F (21·5 °C). The anaesthetist is for much of the time less active than the surgeon who bears the continuing burden of the anxiety and responsibility of the operation as well as having to work in a warmer area of the room. By contrast the anaesthetist may be sitting in such a position that he is directly exposed to the air inlets that may be immediately over his head. One simple answer to these differing personal requirements among the operating room team is that they should dress accordingly; the anaesthetist, for example, may need warmer clothing. This need for adaptation of the climatic requirements of each individual becomes most important when we consider the patient himself. It is unlikely that full control of the patient's requirements of heat loss or heat gain can be achieved by adjustment of the thermal environment of the operating room, and if we are to aim to provide what is best for the patient this can only be achieved by direct methods applied to him. It is not desirable to consider this important matter more fully in this paper; it must suffice to draw attention to it now and to deal with it more fully in another article.

In addition to the varying factors that require differing conditions for the members of the operating room team we also have to face the individual preferences of the surgeon. Surgeons differ widely in what they require; many find that a comfortable working temperature is 18·5–21 °C, and it will be remembered that Wyon et al. (1968) found that most surgeons were comfortable at temperatures around 66·5 °F (19 °C) in their survey of 30 operating suites and 85 operating rooms. Some surgeons do not like a low temperature and prefer a range of 21–22 °C. It should be remembered that unless the efficiency of the surgeon is impaired by environmental conditions which are uncomfortable for him it is the effect of the temperature and humidity of the operating room on the patient that is really important. The patient may be overheated, even as far as being exposed to hyperpyrexia, or he may be chilled. Paediatric surgeons are well aware of this and it is their practice to have the theatre warmer (22–24 °C) for infants or children, especially when the operation being done or the condition being treated (e.g. burns) involves exposure and produces excessive heat loss.

Here it is necessary to consider what should be the critical ambient temperature. This has been considered and assessed by Morris and Wilkey (1970) and Morris (1971) as being 21 °C, and they recommend that to prevent intra-operative hypothermia the operating room temperature should be between 21 and 24 °C. If we accept 21 °C as the critical ambient temperature desirable for an adult this would have to be modified upwards for infants and children. Where an ambient temperature of as high as 24 °C could be accepted for the safer conduct of a high risk procedure on an ill child it would ordinarily be unacceptably warm and uncomfortable for an operating room team, even though temperatures as high or even higher than this are often inflicted on the occupants in many operating rooms. Observations will be given in a later article that do not give support to the practice of increasing the ambient temperature to prevent heat loss. In fact the principle of the exercise has been fully presented by Charles Lamb in his 'dissertation on roast pork'.

There should be wide general appreciation and awareness of the need for optimal climatic conditions in the operating room and it is suggested that it should be the proper duty and responsibility of the surgeon to make it a rule to acquaint himself with the exact conditions pertaining when he begins an operating session instead of paying little or no attention to them except to complain later that the room is too hot or too cold or too humid. For most routine operations and for short operations the climatic conditions that the patient undergoes do not matter greatly. Nature is prodigal in her endowments and patients can endure much without any great harm being done. However, if a long, complex and dangerous procedure is being undertaken, especially on an ill or a poor risk patient, then it should be incumbent upon the surgeon to acquaint himself clearly and fully with the environmental conditions in the operating room, just as he should know the relevant features of the patient's clinical state such as pulse rate, blood pressure etc., and just as the captain of a ship must know the weather conditions, the state of the tides and the draught of water.

Apart from the thermal and humidity levels it is necessary to consider the mode and site of the delivery of conditioned air into the operating room.

The use of laminar air flow, whether vertical or horizontal, is at present predominantly used for control of infectivity and it would not be useful to discuss it more fully now. At the same time it must have considerable climatic significance apart from the control of infectivity and so discussion will be necessary later.

The usual arrangement of air inlets is either by separate circular or square diffusers in the ceiling or by lateral inlets sited high up on one or more walls. The air escapes either via natural outlets such as doors, etc. or by planned outlet grilles or by pressure-relief flap valves.

It is important that the delivery of air from the inlets should not be too violent or too concentrated, and that the inlets should be sufficient in number and size to ensure a gentle inflow. Their siting must also be considered carefully and should certainly not be left for the decision of the engineer on his own. Care should be taken that they are sited in the most 'neutral' part of the room and not directly over the heads of, for example, the anaesthetists. It is tempting to the engineer if an observation dome is present to avail himself of its circular form to carry the trunking and to position the inlets around the base of the dome. This will mean that all the team who are located under the periphery of the dome are exposed to a direct down draught. In general such ceiling inlets should be more peripherally sited. Careful thought must also be given to the size and siting of air inlets on the side walls; they should be large enough and so placed that a stream of turbulent air is avoided. It is now possible to be supplied with air diffusers that do not blow down directly upon those underneath, but can direct the air inflow horizontally or in a lateral direction (*Fig.* 1). This is a simple but important consideration.

Enough has been said already to make it mandatory to provide fully conditioned air for the intensive care unit. The mode of its provision demands as much thought as in the operating room. First of all it is necessary to emphasize that the intensive care unit may need much more planned protection from harmful or unfavourable external environmental influences than does the operating room. The main weather aspect should be deliberately considered and it should not be overlooked whether it is, for example, south or north. Also any differences within the unit of the various weather aspects must be considered and protection be provided, where needed, either by appropriate shading or by double glazing. This alone can produce great benefits.

If the unit contains separate or individual rooms these will need special consideration. A common form of air inlet provided is a circular or square diffuser in the ceiling sited immediately over the patient's bed (*Fig.* 1). It is scarcely necessary to do more than draw attention to such a gross error. Similarly, in a larger ward housing several patients the siting of ceiling diffusers can be equally objectionable, not only for the patients but also for the nurses. It has already been pointed out that air diffusers can now be supplied that deliver a stream horizontal to the ceiling and *not* directly downwards. The views and experiences of the nurses are often not consulted in assessing the good or bad points of the construction of such a ward, but if asked they may be immediately forthcoming about the nuisance and drawbacks of ill-placed ceiling inlet diffusers. It will be discovered that they often find it necessary to move the patient's bed so that he may not be exposed directly to a downward air stream. The nurse may complain bitterly of this and can find it especially unwelcome if she is sitting or standing beside the bed under a downward air stream.

For reasons such as these it is necessary that the temperature controls should be conveniently adjustable in the ward and in the individual rooms. One objection often raised is that this is undesirable as nurses and others are liable to tinker with and disturb the setting. Nevertheless if the controls are inaccessible an engineer has to be summoned to alter them and this may entail much delay, especially at night.

Lateral grilles in the side walls may be unwelcome unless carefully sited. A form of laterally placed inlet that is often more satisfactory is a long slit across the whole length of one wall. If used in a single room and placed high on the wall above the patient's head it can direct the air stream in an arching fashion that passes completely over the patient and spares him from any direct discomfort while at the same time the room is efficiently ventilated.

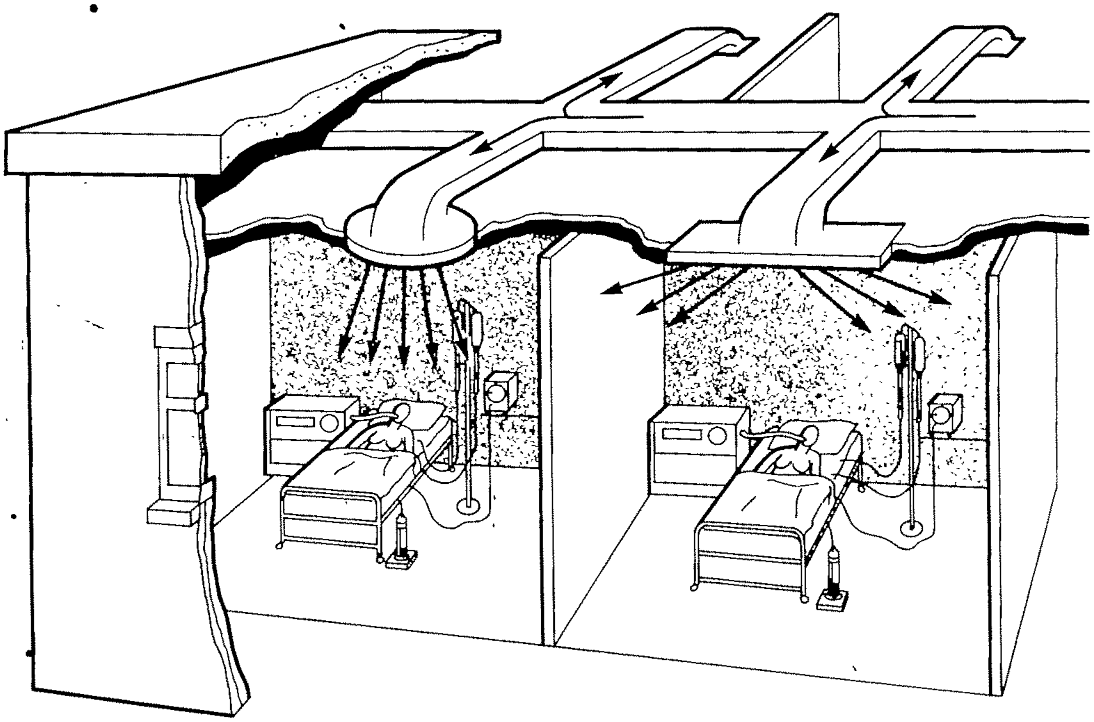

Fig. 1. Diagrammatic representation of a room with a direct down draught of incoming air and how this can and should be prevented by an inlet that gives a horizontal direction to the air flow.

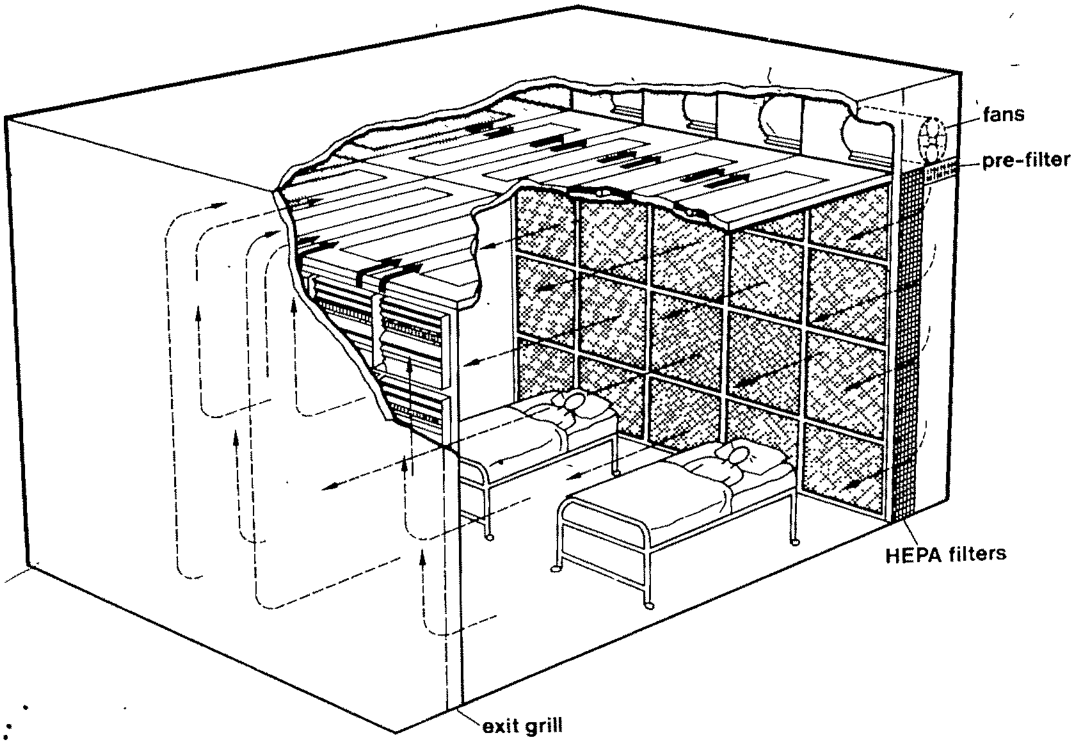

Fig. 2. Diagram showing a room air-conditioned by horizontal laminar flow.

The method that should be especially considered in the intensive care unit is laminar flow. This can be vertical or horizontal but the horizontal flow is likely to be more practical. This is possibly the best means of air-conditioning the intensive care unit (*Fig.* 2). The availability of commercial equipment designed for clean air industrial rooms means that the experience and production methods are available and that the cost need not be excessive. Careful thought should be given to the provision of laminar flow equipment. Many problems may be avoided if early thought is given to its provision while designing or modifying rooms and extra care in design can avoid any undue noise if the fans and humidifiers are carefully sited.

Some observations on peripheral venous pressure using a non-invasive technique: a preliminary report

H. GAYLIS*

SUMMARY

Observations are presented which suggest that peripheral venous pressure can be measured indirectly by a non-invasive technique at the bedside, using a portable Doppler ultrasound flowmeter.

The pressure at which the audio signals are heard over veins on release of the occluding cuff seems to be a measure of peripheral venous pressure. This is supported by showing a correlation between the method and conditions in which raised venous pressure in the lower limb are known to exist. The results of a few direct venous pressure measurements are reported which appear to give added support.

It is suggested that this simple non-invasive technique may be of value in detecting certain cases of deep vein thrombosis of the lower extremities.

WHILE arterial blood pressure can be accurately measured by non-invasive techniques, such as sphygmomanometry, oscillometry and the Doppler ultrasound flowmeter, venous pressure can only be reliably measured by cannulation or puncture of veins, using a vertical saline manometer, aneroid manometer or strain gauge transducer. The measurement of venous pressure by a non-invasive technique could have great value in the diagnosis of certain diseases such as venous thrombosis. The purpose of this paper is to present a number of observations which suggest that peripheral venous pressure may be measured indirectly by non-invasive technique at the bedside, using a portable Doppler ultrasound flowmeter.

Materials and methods

A Doppler probe of a 10-MHz flowmeter is placed over the posterior tibial artery behind the medial malleolus (*Fig.* 1). Because the posterior tibial veins usually lie adjacent to the artery the Doppler probe will detect blood velocity changes in both the artery and the vein. An inflatable cuff just above the ankle is inflated to above systolic pressure. The cuff is slowly deflated at a rate of about 5 mm Hg per second. At first the characteristic arterial audio signals in phase with the cardiac cycle are heard. On further deflating the cuff, a superimposed continuous sound is audible at an average cuff pressure of about 30 mm Hg which disappears or fades at pressures varying between 10 and 0 mm Hg. *Fig.* 2 is a recording of the audio signals heard over the posterior tibial artery and vein at the ankle, as displayed on an oscilloscope with a storage memory. The recording was photographed with a Polaroid camera. At *A* the normal arterial audio signals corresponding with each pulse beat can be noted. At *B*, with the cuff inflated above systolic pressure, no flow signals can be seen, thus indicating cessation of

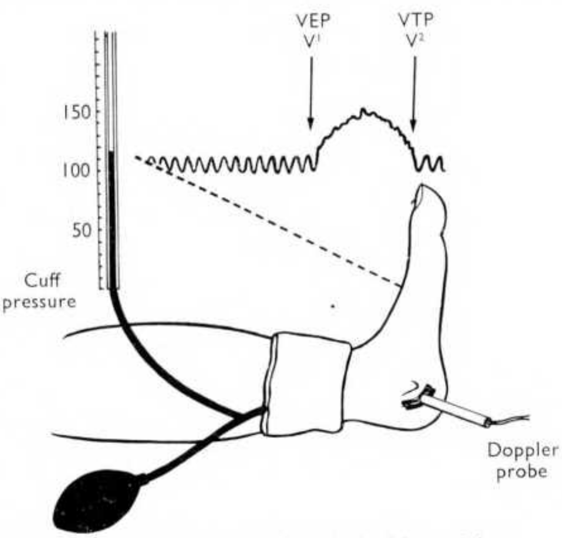

Fig. 1. Diagram to illustrate the method of determining peripheral venous pressures. *VEP* (V^1), Venous escape pressure. *VEP* (V^2), Venous terminal pressure.

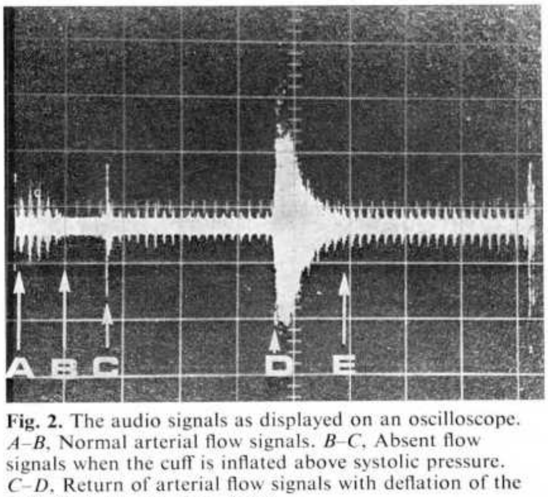

Fig. 2. The audio signals as displayed on an oscilloscope. *A–B*, Normal arterial flow signals. *B–C*, Absent flow signals when the cuff is inflated above systolic pressure. *C–D*, Return of arterial flow signals with deflation of the cuff. *D–E*, Venous flow signal.

* Department of Surgery, University of Witwatersrand and the General Hospital, Johannesburg.

arterial blood flow. At *C*, with the cuff pressure deflated below systolic arterial pressure, audio signals in phase with arterial pulsation reappear. As the cuff is further deflated, another signal (*D*) is seen which rapidly reaches a crescendo and, on further deflating the cuff, disappears at a cuff pressure of approximately 10 mm Hg.

That the onset of this second sound was caused by escape of venous blood under increased pressure behind the cuff is the likely explanation of the phenomenon. This is supported by the following observations. The posterior tibial veins accompany the posterior tibial artery and not infrequently 'S' sounds (spontaneous flow signals in phase with respiration) are audible in this region. 'A' sounds (augmented signals) can also be produced quite readily by sharp pressure on the soft tissues proximal to this region or by compression of the forefoot. Audio signals can also be heard by placing the probe over other visible veins on the dorsum of the foot such as the saphenous or anterior tibial veins. Futhermore, reversal of flow, coinciding with the venous audio signal, was confirmed with the directional Doppler.

Not only did it seem that the onset of the 'venous' audio signal coincided with the escape of venous blood behind the cuff, but it also seemed possible that the disappearance or attenuation of the venous sound was caused by equalization of venous pressure and thus venous velocity flow proximal and distal to the cuff. It thus seemed that the cuff pressure at which the venous audio signal disappeared or became attenuated could be a measure of peripheral venous pressure. If the supposition was correct then the method could clearly have value as a non-invasive technique of measuring peripheral venous pressure and that it could be of use in the diagnosis of some cases of deep vein thrombosis of the extremities.

To determine whether the disappearance of the 'venous' signal was an index of peripheral venous pressure, normal values would have to be established and then the method would have to be tested in limbs known to have an increase in venous pressure.

1. *Normal 'venous' cuff pressures*

Fifty patients who had no clinical evidence of venous or arterial disease of the lower extremities had both lower limbs evaluated. The patients lay supine with the head raised on one flat pillow. The reference level, considered as the right atrium, was chosen as a point half the anteroposterior diameter of the chest at the middle of the sternum. The vein under test, the posterior tibial vein at the medial malleolus of the ankle, was placed at the same level as this reference plane. The temperature and humidity of the room were not controlled. The Doppler ultrasound flowmeter used in the experiment was a Parks Model 802 or 803 (10 MHz) and the probes were either of the pencil or flat type. The rate of deflation of the collecting cuff was not accurately controlled but was approximately that used in deflating a cuff for determining normal blood pressure, i.e. ±5 mm/second.

0	40	5	20	10	30	10	20	15	35	5	35	

The onset of the venous audio signal V^1 (venou escape pressure) and the disappearance of the venou audio signal V^2 (venous terminal pressure) wer recorded to the nearest 5 mm Hg. *Table I* shows th relevant data in each series of limbs and, as can b seen, the average V^1 pressure is about 30 mm Hg an the average V^2 pressure about 9 mm Hg. Eight patient had arterial hypertension but in this group there wa no increase in these two values. Whereas the V^1 pressures varied, the variation depending mainly on th rate of deflation of the collecting cuff, the V^2 pressure remained more constant. Furthermore, there wa good correlation between the values obtained in eac pair of limbs.

2. *The response to induced venous obstruction*

A collecting cuff was placed around the upper calf i 6 patients and various degrees of venous occlusio produced distally by varying the pressure of the cal cuff. The V^1 and V^2 cuff pressures were then recorde at the ankle at calf pressures varying from 0 t 100 mm Hg. *Table II* shows the V^1 and V^2 pressure relative to the calf pressures, and *Fig.* 3 a graphi representation of the data, but recording only the V pressures. As can be seen, the V^2 cuff pressure correlate with the different degrees of venous obstruction produced by the calf collecting cuff.

3. *Deep vein thrombosis*

The pressures at which the V^1 and V^2 signals are hear were recorded in 11 patients suffering from deep vei thrombosis in the upper and lower extremities. In patients the deep veins of one or both lower extrem ties were affected and in 2 patients the axillary sub clavian segments were occluded. The diagnosis wa made on clinical grounds alone, except in one patie who had in addition confirmatory venograph evidence. In 8 of the 11 patients tested the 'venou pressures were elevated (*Table III*).

Table III: V^1 AND V^2 CUFF PRESSURES IN 11 PATIENTS WITH CLINICAL DEEP VEIN OBSTRUCTION

	60	29	30

In *Cases* 3 and 4 a collecting cuff was applied and inflated to the levels recorded.

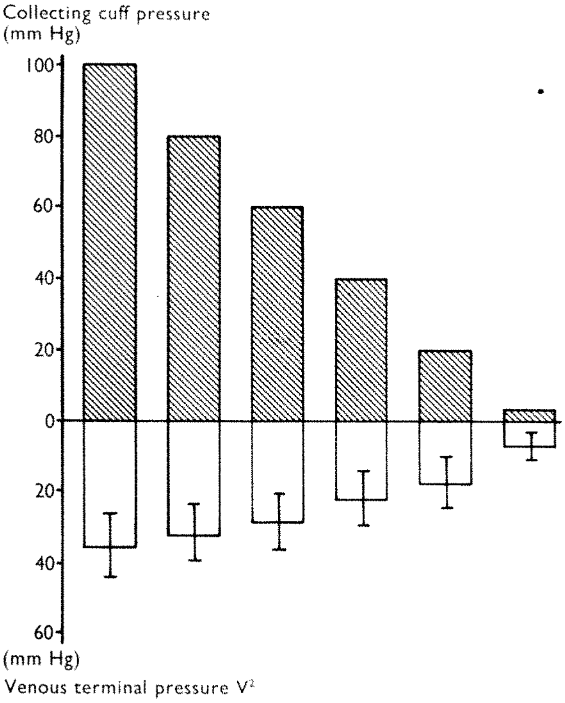

Fig. 3. Correlation between the V^2 pressures and the collecting cuff pressure. Each vertical bar represents the mean of 6 patients.

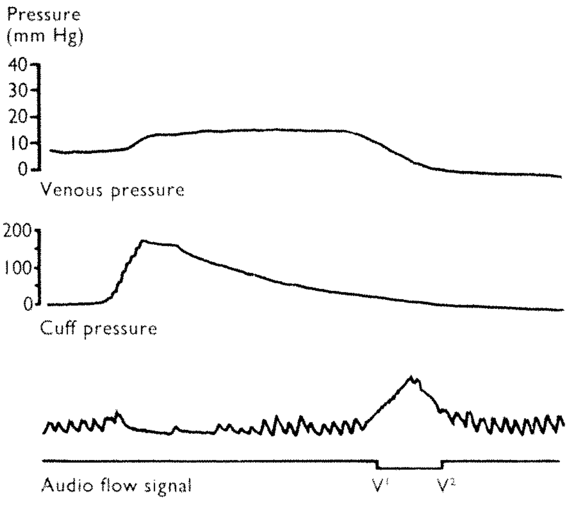

Fig. 4. Simultaneous instantaneous recordings of direct venous pressure, cuff pressure, flow signals and audio venous signals V^1 and V^2 as recorded by the observer. Note that the V^1 and V^2 observer audio signals correspond with the venous flow signal and with the venous escape and venous terminal pressures.

4. *Direct venous pressure measurements*

In 4 patients the venous cuff pressures (V^2) were correlated with venous pressures recorded by direct vertical saline manometry. The pressures were measured in a vein on the dorsum of the foot with the patient in the supine position. The resting venous pressures correlated fairly well with the V^2 pressures, and on increasing the peripheral venous pressure by inflating the collecting cuff on the calf there was a rise in peripheral venous pressure which corresponded fairly well with the V^2 signals (*Table IV*).

5. *Simultaneous instantaneous recordings*

In 3 patients simultaneous instantaneous recordings were made of the four relevant parameters. The patients were tested in the supine position and the parameters recorded were the direct intravenous pressure, the ankle cuff pressure, the arterial and venous flow signals and the onset and disappearance of the venous audio signal as heard by the observer. The pressures were measured by strain gauge transducers and the audio signal recorded on a DC recorder with a deflection factor of 50 MV/CM. The apparatus used to record the above parameters was a Beckman Dynagraph Recorder (Type RM). The venous pressures were recorded through a needle or cannula inserted into a vein on the dorsum of the foot.

Fig. 4 shows an average recording of the parameters investigated. As the cuff pressure is increased by the manually inflated cuff, there is a corresponding rise in venous pressure. When the cuff pressure rises above systolic arterial pressure, all flow signals disappear. On release of the cuff pressure, arterial flow signals in phase with the arterial pulse are clearly seen. The venous pressure now begins to increase and when the pressure distal to the cuff exceeds the cuff pressure, venous blood escapes and this is accompanied by the appearance of the escape flow signal (V^1) which is a high frequency continuous signal. As the venous pressure decreases and becomes static, the venous audio signal V^2 disappears to be replaced by normal arterial signals. The onset and disappearance of the venous audio signal as heard by an observer are seen to coincide with the flow signal and the changes in venous pressure.

Discussion

When an inflatable cuff which has been pumped above systolic pressure is deflated, arterial blood enters the part distal to the cuff when the systolic pressure exceeds the cuff pressure. If the cuff is not completely deflated the part distal to the cuff becomes distended with venous blood until the venous blood pressure exceeds the cuff pressure and blood begins to escape. The velocity of this escaping venous blood just behind the cuff is therefore increased and this change effectively accounts for the onset of the venous audio signal (V^1). As the venous pressure decreases on further deflating the cuff, the velocity flow presumably also decreases, and when the pressure behind the cuff returns to normal, the velocity flow reaches a steady state. This accounts for the disappearance of the venous signal (V^2), and the cuff pressure at which this occurs should signify the approximate peripheral venous pressure.

The supposition that the V^2 signal is an index of peripheral venous pressure is supported by the clinical results of this investigation and more importantly by direct venous pressure tracings. With regard to the clinical evidence the mean V^2 pressure in 100 normal limbs was 9 mm Hg (s.d. ± 4), and in each pair of limbs the correlation was good. These mean pressures correlate with direct venous pressures measured by others in unrelated studies. Winsor and Burch (1946) and Ochsner et al. (1951), in a study of venous pressures in peripheral veins, reported mean pressures of 150 mm H_2O (11·02 mm Hg) and 126 mm H_2O (9·26 mm Hg) respectively at the great saphenous vein at the ankle.

The correlation between the V^2 pressures and the graded increases in venous hypertension produced by varying the pressure of the calf collecting cuff (*Table II* and *Fig.* 3) is also further evidence supporting the hypothesis that the method is a measure of peripheral venous pressure. Further clinical support seems to be afforded by the few cases of deep vein thrombosis studied so far. In 8 of the 11 patients the V^2 cuff pressure was increased.

The correlation between the V^2 venous signals and the direct venous pressure readings (*Table IV*) and between the instantaneous simultaneous recordings of the direct venous pressures, cuff pressures and audio flow signals (*Fig.* 4) is good supportive evidence that the V^2 audio signal is an index of peripheral venous pressure.

The venous escape pressure V^1, however, does not always correlate with direct venous pressure, and the venous pressure may continue to rise after the onset of the signal as was shown in several recordings. This is understandable, considering that on deflating the cuff the arterial input may be greater than the venous outflow. Thus the V^1 audio signal simply indicates that venous blood is escaping past the cuff and that it is not necessarily a measure of the venous pressure at that point in time. Another observation of interest was that in some of the tracings the venous pressure, after deflation, fell below the venous pressure baseline before the cuff was inflated. It is thought that this phenomenon was the result of vasodilatation of veins caused either by mechanical distension of veins or by an accumulation of metabolites during the short period of circulatory arrest by the cuff.

With regard to the direct venous measurements, these were all done in superficial veins on the dorsum of the foot, whereas the venous signals were recorded over the posterior tibial veins which belong to the deep venous system. Objection may therefore be made to these two comparisons, but it is difficult to conceive of two different pressure systems in the superficial and deep systems, having regard to the abundant communications between the superficial and the deep system of veins. The exception, of course, would be where there was spasm of the superficial veins, when the pressure of these would fall to zero. Fegan (1967) stated that the deep and superficial pressures are equal in the resting limb in the erect subject.

Although the evidence strongly suggests a relatively good correlation between the V^2 audio signal and venous pressure, it should not be assumed that the cuff pressure at which the V^2 signal is heard is an accurate reflection of direct venous pressure. The susceptibility of veins, especially superficial veins, to change their dimension and cross-sectional area make the reliable measurement of venous pressure, velocity and volume very difficult. The mere introduction of a needle or cannula into superficial veins often causes spasm, which was frequently noted in these experiments. Moderate environmental changes and psychological factors have the same influence.

One of the difficulties with the cuff method in the normal supine position is that the disappearance of the audio signal is not always clear-cut and is subject to an observer error of ± 5 mm Hg. Further, in some cases the end-point was not at all determinable because the sound did not disappear even at cuff pressures of zero. However, when venous hypertension was induced by the application of a collecting cuff, the V^2 audio signals were more often discernible. The inability to discern the V^2 signal in some patients was probably related to a high venous flow in the resting state and this was often observed in patients with vasodilated extremities and also in those who had had a sympathectomy. Whereas the V^1 audio signal could be varied by altering the rate of cuff deflection, the V^2 audio signal was not subject to the same variation. This variation in V^1 cuff pressures on altering the state of deflation is understandable, considering that a greater volume of venous blood is allowed to accumulate when the rate of deflation is slowed.

All the venous audio signals in this experiment were recorded over the posterior tibial veins because venous signals were more readily detected here than over other veins on the dorsum of the foot. Venous signals are detectable over the long saphenous and other veins on the dorsum, but these are more prone to go into spasm. When venous signals are recorded over the long saphenous vein at the medial malleolus, however, the V^1 and V^2 audio signals usually correspond with those obtained over the posterior tibial veins. In some cases where they did not correspond this was thought to be due to a difference in the cuff pressure required to compress the two different system of veins. The long saphenous vein is subcutaneous and lies on bone and therefore less pressure is required to compress it than the more deeply situated posterior tibial veins, which lie protected under the deep fascia.

An interesting feature on deflating the ankle cuff was the occasional observation of an 'audio gap', reminiscent of the auscultatory gap noted on recording arterial blood pressure. It was thought at first that this was an artefact caused by the cuff in which part of the cuff was fully deflated. However, this audio gap could not be abolished by altering the position or the type of the cuff. This anomaly remains unexplained at present.

In about 15 per cent of limbs the venous audio signals could not be heard over the posterior tibial veins. The reasons for this are open to speculation and could be accounted for by some anatomical anomaly, by occlusion by previous venous thrombosis or by too great a depth of the vein from the skin and thus from the probe.

With regard to positioning the probe over the vein it is essential that no undue pressure be produced. This may cause narrowing of the vein which could alter the velocity flow to give false values. Accordingly the probes were lightly positioned over the vein, and in the instantaneous simultaneous recordings of audio signals, flat probes were used which were lightly placed on the skin with coupling gel and the probe held in position with adhesive tape.

In conclusion it would appear that this non-invasive technique of assessing peripheral venous pressure using the Doppler ultrasound flowmeter may be of value in screening patients suspected of suffering from deep vein thrombosis. Although it has not been shown that the values obtained with this technique are absolute, there appears to be relatively good correlation. The technique may be of value for detecting certain cases of deep vein thrombosis, but it could obviously not detect all, having regard to the fact that deep vein thrombosis may exist, without increased venous pressure, for example where the thrombus is of the non-occlusive type or where the collateral circulation is good. A trial is now in progress to assess further the possibilities of this interesting observation.

Acknowledgements

I am grateful to Professor D. J. du Plessis for his encouragement and comments and to Mr C. D. Bremner for his technical assistance with recordings.

Report of a family with inherited medullary carcinoma of the thyroid and phaeochromocytoma

J. M. BEAUGIE, P. E. BELCHETZ, C. L. BROWN, R. J. FRANKEL
AND MARGARET H. LLOYD*

SUMMARY

A family in which several members have medullary carcinoma and phaeochromocytoma is described. Four of the 5 patients in this family who had a phaeochromocytoma have died; in one of these the medullary carcinoma may have contributed to death but in general the thyroid cancers were slow growing. In our experience successful diagnosis and treatment of the phaeochromocytomas have presented the greatest challenge. The welfare of future generations with this syndrome would seem to depend upon regular clinical and biochemical surveillance of the individuals and expeditious diagnosis and treatment of their tumours, particularly the phaeochromocytomas.

THE association of medullary carcinoma of the thyroid with phaeochromocytoma of the adrenal constitutes a well-known familial syndrome (Sipple, 1961; Williams, 1965; Williams et al., 1966; Block et al., 1968; Williams, 1970; Melvin et al., 1971; Keiser et al., 1973) inherited through an autosomal dominant gene (Steiner et al., 1968). The disease is therefore seen in either sex and is likely to manifest itself in half the offspring of an affected individual (Keiser et al., 1973). The tumours in the thyroid and adrenal are often bilateral and multiple, and other stigmata of the syndrome include neuromatous malformations at mucocutaneous junctions (Williams and Pollock, 1966) and parathyroid hyperplasia or adenoma (Gorlin and Mirkin, 1972; Keiser et al., 1973). These tumours have been grouped together forming the syndrome 'multiple endocrine neoplasia or adenopathy type II' (Steiner et al., 1968), in contrast to the tumours of 'multiple endocrine neoplasia type I' which includes the parathyroid, pancreatic and anterior pituitary adenomas associated with peptic ulcers (Wermer, 1954, 1963).

Medullary carcinoma is a malignant tumour of the parafollicular or 'C' cell of the thyroid (Williams, 1966a). The parafollicular cell appears to migrate from the neural crest in the embryo (Pearse, 1966); it secretes calcitonin (Foster et al., 1964) and is a so-called 'APUD' cell because it is able to concentrate and decarboxylate amine precursors (Pearse and Welbourn, 1973). Medullary carcinoma regularly secretes calcitonin and may also secrete adrenocorticotrophic hormone (Williams, Morales and Horn, 1968), prostaglandins (Williams, Karin and Sandler, 1968), serotonin (5-hydroxytryptamine) (Moertel et al. 1965) and histaminase (Baylin et al., 1970). Nearly one-third of the patients suffer from diarrhoea, perhaps due to one or more of these hormones
chemical substances (Williams, 1966b).

In this paper we present some cases of the famili
syndrome seen at The London Hospital. There are,
course, other and larger families in the world liter
ture (for example, Block et al., 1968; Steiner et al
1968; Melvin et al., 1971; Keiser et al., 1973). O
family is perhaps the largest and most complete wi
a high degree of penetrance of the gene to be report
in Great Britain. The most difficult problem h
proved to be the diagnosis and treatment of th
phaeochromocytomas which will therefore be co
sidered in some detail.

Biochemical assay methods

Vanillylmandelic acid (VMA) was estimated in uri
collected over 24 hours into a bottle containing 1
15 ml of concentrated hydrochloric acid and assay
by a modification of Pisano's method (Connelian a
Godfrey, 1964). The normal range is 3–8 mg/24 hou
Other urinary catecholamine metabolites we
measured semi-quantitively by two-dimensional pap
chromatography (Robinson and Smith, 1962). Calcit
nin in plasma and tissue was measured by Professor
McIntyre using a specific radio-immunoassay. T
normal value for plasma calcitonin is less th
0·5 ng/ml and for normal thyroid less than 1 ng/
Adrenocorticotrophic hormone (ACTH) in plas
and tissue was measured by Dr J. G. Ratcliffe usi
N-terminal specific antibody radio-immunoassay aft
extraction with porous glass (Ratcliffe and Edwar
1971). Normal plasma ACTH is less than 70 pg/ml.

Members of the family studied

Two generations of the family are known to
affected by medullary carcinoma with phaeochrom
cytoma (*Fig.* 1). The father (H. B. sen.) had 6 childr
of whom all except the youngest have had at least o
type of tumour. There are 9 children in the thi
generation who are under the age of 18 years and o
has a goitre, but since she is mentally subnormal it h
not been possible to investigate her. No clinical
biochemical evidence of medullary carcinoma
phaeochromocytoma has been found so far in t
other 8 children.

* Departments of Medicine and Surgery, and the Institute
Pathology, The London Hospital, London.
Present address of P. E. Belchetz: Northwick Park Hospi
Harrow, Middlesex.
Present address of R. J. Frankel: St George's Hospi
London.

H. B. sen. died suddenly at home aged 67 years. At a coroner's autopsy bilateral phaeochromocytomas were found and confirmed histologically. The state of his thyroid was not reported.

E. S., his eldest daughter, died suddenly at another hospital aged 46 years. The post-mortem revealed carcinoma of the thyroid with pulmonary and adrenal metastases. This diagnosis is unconfirmed histologically but, considering her family background, she probably had medullary carcinoma and bilateral phaeochromocytomas.

H. B. jun., the eldest son, died in The London Hospital aged 43 years. He was admitted from the Diabetic Clinic, which he had attended for many years, for investigation of hypertension. This included a phentolamine test which was positive, following which he developed profound hypotension and died. At post-mortem there were bilateral medullary carcinomas in the thyroid and bilateral phaeochromocytomas.

J. S., the second daughter, is alive aged 41 years. For at least 18 years she has had a swelling in the right lobe of the thyroid. There were no symptoms of phaeochromocytoma but her blood pressure was 170/110. The 24-hour ^{131}I thyroid uptake was 68 per cent (normal 34–55 per cent) and a scan showed non-functioning areas in both lobes. Her protein-bound iodine was normal and thyroid auto-immune microsomal antibodies were positive by the fluorescent technique. Her plasma calcitonin was 7·7 ng/ml. Investigations of her hypertension revealed a normal IVP and blood urea and no proteinuria. Repeated VMA levels were also normal.

A total thyroidectomy was performed (*Fig.* 2). The medullary carcinoma in the right lobe was 3·7 cm in diameter and that in the left 2·5 cm. There was some calcification in the tumours, marked lymphocytic infiltration in the thyroid parenchyma and microscopic foci of medullary carcinoma near the main tumours. The tumour calcitonin level was 10 000 ng/mg. She is now in good health, without evidence of thyroid cancer or phaeochromocytoma. Her blood pressure 3 years after thyroidectomy is 170/85 mm Hg and VMA excretion is within normal limits.

A. B., the second son, died at the age of 38 years. He had a solitary nodule in the right inferior pole of his thyroid of which he was not aware, and for 6 years had suffered the symptoms of phaeochromocytoma. A ^{131}I thyroid scan confirmed a cold nodule, and the plasma calcitonin level was 1 ng/ml. His blood pressure was 140/90–170/110 and the phaeochromocytoma was confirmed by 24-hour urinary VMA estimations of 8·4, 9·4 and 12·0 mg and excessive urinary levels of normetadrenaline and metadrenaline. The phenotolamine test was positive. The 24-hour urinary 17-oxogenic steroid level was 20·5 mg and 17-oxosteroid 14·2 mg (normal 7–20 mg and 5–20 mg respectively).

A. B.'s phaeochromocytomas were treated by bilateral adrenalectomy; first the left was removed at laparotomy, followed 2 weeks later by the right through a costophrenic approach. The right adrenal weighed 19·0 g and the left 5·5 g (normal weight up to 4·5 g). Apart from several phaeochromocytomas, there was a marked increase in compact cells of the cortex, signifying excessive ACTH stimulation (*Fig.* 3). Afterwards, the patient was clinically well, taking cortisone acetate 12·5 mg three times daily and fludrocortisone 0·1 mg daily, but the plasma ACTH was very high, being 335 pg/ml at 9.00 hours (normal 70 pg/ml) and 195 pg/ml at midnight.

Three months after adrenalectomy near total thyroidectomy was performed. The medullary carcinoma in the right lobe measured 3 cm in diameter and the left 0·5 cm (*Figs.* 2, 4). The tumour contained ACTH to a level of 0·1 pg/g of tissue, which is greater than in normal tissue (Rees, 1974).

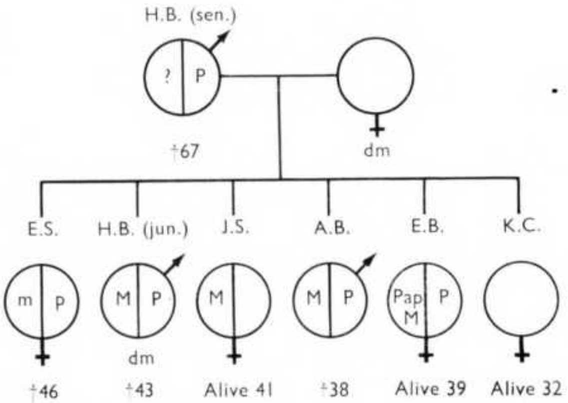

Fig. 1. Family tree. *M*, Proved medullary carcinoma. *P*, Proved phaeochromocytoma. *m*, Suspected medullary carcinoma. *p*, Suspected phaeochromocytoma. *dm*, Diabetes mellitus. *Pap.*, Papillary carcinoma.

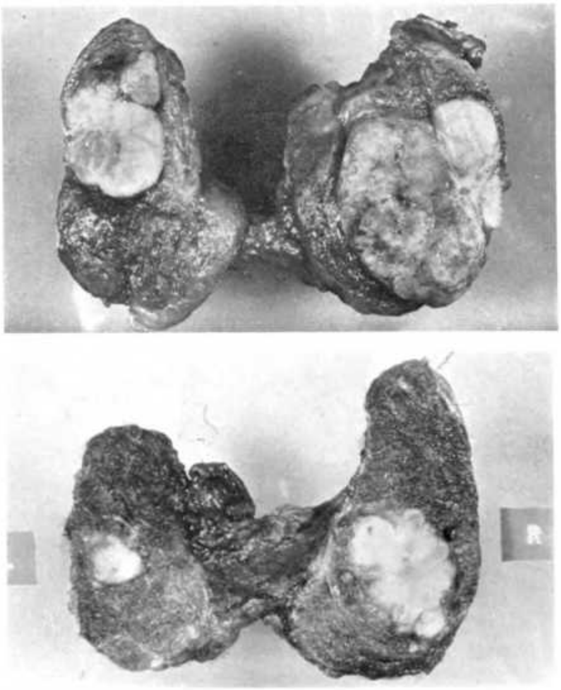

Fig. 2. Photographs of the thyroidectomy specimens from J. S. (*above*) and A. B. (*below*) showing the similarity in location of the main medullary carcinomas in both lateral lobes of the two glands.

Six months later A. B. developed Addisonian pigmentation even though his steroid replacement dose had been raised to 50 mg of cortisone acetate daily. His plasma ACTH level at that time was very high (890 pg/ml) but was suppressible by increasing doses of dexamethazone to 50 pg/ml when he took 16 mg of dexamethazone daily. These levels when the patient was apparently having adequate steroid replacement suggested the presence of ectopic ACTH-secreting tissue; a suggestion reinforced by the finding of an enlarged liver and a ^{198}Au liver scan with an abnormal uptake pattern. In the chest X-ray the left hemidiaphragm was raised.

His clinical condition was stable for 18 months before he died suddenly despite large doses of intravenous hydrocortisone. At autopsy there was no medullary carcinoma or other neoplasm in the liver which could have secreted ACTH but there was a large subphrenic abscess on the left side. The pituitary contained many 'shock' cells, suggesting that it had been secreting excessive quantities of ACTH. The acidophils were well granulated and the thyrotroph cells were normal, indicating that thyroid replacement therapy had been adequate.

E. B. is the third daughter now aged 39 years. She was 8 years old when a goitre was noticed and was eventually treated by subtotal thyroidectomy at the age of 16 years. The specimen

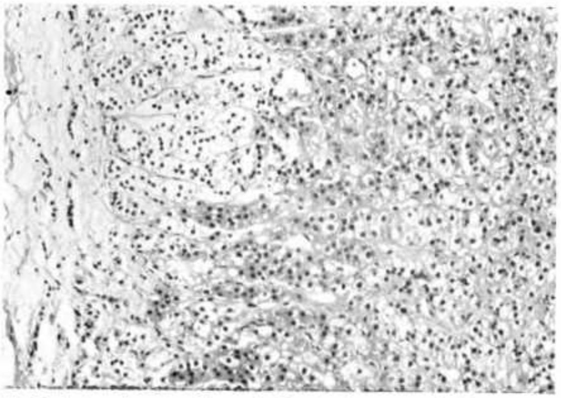

Fig. 3. Adrenal cortex from A. B. showing a marked increase in numbers of compact cells, in places forming columns extending out to the capsule. HE. (× 88.)

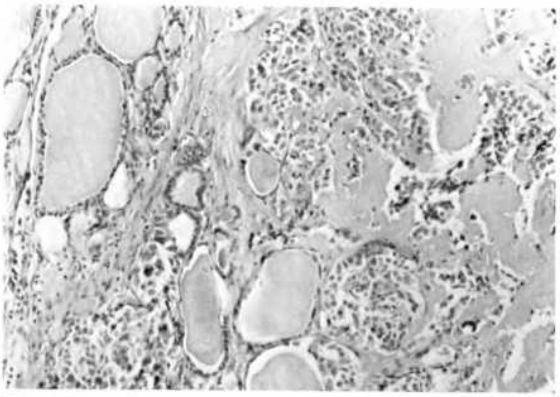

Fig. 4. Edge of tumour from A. B. showing uniform carcinoma cells separated by masses of amyloid and nvading surrounding thyroid follicles. HE. (× 88.)

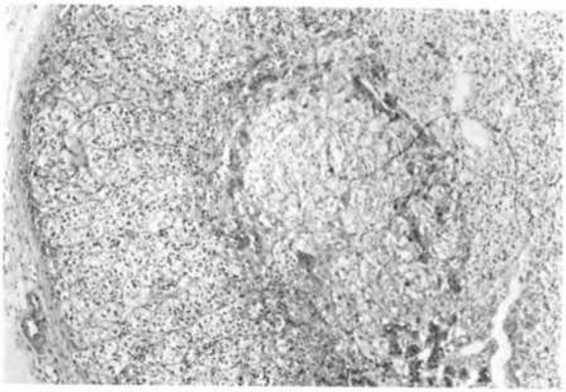

Fig. 5. Adrenal from E. B. which was macroscopically normal, but showing one of several microscopic phaeochromocytomas. HE. (× 41.)

contained a papillary carcinoma confined to the thyroid. During the next 12 years several metastatic lymph nodes were removed, culminating in bilateral dissections of the neck nodes 13 years ago. On further study this last specimen was found to contain not only papillary carcinoma but also multiple discrete nodules of medullary carcinoma in the thyroid remnant. Since then she has needed one further excision of a lymph node containing papillary carcinoma, but no further medullary carcinoma has been found.

E. B. had suffered the symptoms of phaeochromocytoma for 12 years and her blood pressure varied between 150/100 and 210/130. The diagnosis was confirmed by a 24-hour urinary VMA excretion of 29 mg and an excess of both normetadrenaline and metadrenaline in the urinary chromatogram. A phentolamine test was not done. She was treated by bilateral adrenalectomy; the right gland weighed 183 g and contained two phaeochromocytomas, and the left was normal in size and macroscopic appearance, but contained several microscopic tumours (*Fig.* 5). Following operation her blood pressure returned to normal and remains so 3 years later.

K. C. is the youngest daughter aged 32. She has no clinical or biochemical evidence of thyroid or adrenal disease.

Discussion

This family shows a very high incidence of medullary carcinomas and phaeochromocytomas when compared with some others (Steiner et al., 1968; Melvin et al., 1971; Keiser et al., 1973), but differs from them in having no recorded parathyroid abnormalities or mucosal neuromas. Our kindred found so far is small compared with the 256 known members of one family (Keiser et al., 1973) of which 44 were examined and found to suffer from 25 medullary carcinomas, 11 phaeochromocytomas and 16 parathyroid abnormalities with 6 of the patients having all three stigmata. This latter kindred is not regarded as complete and the members traced so far may be as little as one-quarter of the family at risk, leaving perhaps 130 affected but undetected living relatives. In another large kindred (Steiner et al., 1968) 186 members were found to suffer from 5 medullary carcinomas, 10 proved and 15 probable phaeochromocytomas and 2 cases of parathyroid hyperplasia. Searching a kindred for new cases, therefore, is likely to be rewarding but the proportion of positive results does vary from family to family. The first member of the family to come to light is perhaps the most unfortunate because his doctors will not be so aware of the possible abnormalities as when seeing subsequent members. In our family H. B. jun. was the first to be seen by us and he died following a phentolamine test before he was recognized as a familial case; both members of the family who died beforehand elsewhere were not suspected of having a familial disease. In our family, therefore, 3 members died before the familial nature of the condition was recognized.

Any patient who presents with a thyroid nodule which is suspicious of carcinoma and particularly one which is thought or proved to be a medullary carcinoma must be screened for hypertension and asked for a family history of thyroid and adrenal operations and cases of sudden death. Any new patient with a phaeochromocytoma should be asked the same questions. Once the clinical diagnosis has been made it should be confirmed not by the phentolamine test as in H. B. jun., who had a fatal reaction, but by an examination of urine for products of catecholamine metabolism. Provided that the urine is kept at a pH below 3 and sensitive chemical assay methods are used, a near 100 per cent diagnostic accuracy has been reported without false positive findings (Freier and Harrison, 1973). Also the phentolamine test may give false positive results in other hypertensive patients (Guazzi et al., 1973) and should only be performed with an intravenous infusion of physiological saline running to correct hypovolaemic hypotension.

Since phaeochromocytomas can be suddenly lethal they should be treated first (Keiser et al., 1973). Bilateral adrenalectomy is required because tumours are usually situated within both adrenal glands and may be of microscopic size. Localization of the tumours by special tests is probably unnecessary and may be dangerous, and the final arbitrator is usually the surgeon's fingers (DeQuattro, 1972). Adrenalectomy is safest when performed through a thoracophrenic incision with the patient placed in the lateral position, so that adrenal veins can be ligated before the tumour is disturbed, though some authors recommend a transabdominal approach (Keiser et al., 1973). Both adrenals can be explored in one session through two incisions if the patient is turned from one side to the other and the blood pressure stabilizes after repositioning. In A. B.'s case the first operation was left adrenalectomy through an epigastric midline incision and the fatal subphrenic abscess which occurred is perhaps more likely to follow this approach than the costophrenic route (Welbourn et al., 1971).

The medullary carcinomas in this family were slow growing in that 2 patients had a goitre for 13 and 18 years respectively and there is strong evidence of metastases in only 1 patient (E. S.). With the possible exception of E. B., tumours were bilateral, as expected, and could therefore only be treated by near total thyroidectomy (Keynes and Till, 1971; Keiser et al., 1973). The coincidence of metastasizing papillary carcinoma and medullary carcinoma found in E. B. must be very rare. This case was reported by Williams et al. (1966) as an example of sporadic medullary carcinoma with papillary carcinoma.

In view of the generally slow progress of the medullary thyroid carcinomas our mistaken diagnosis of liver metastases in A. B. 6 months after total thyroidectomy was premature. It was suggested by an abnormal appearance in the ^{198}Au liver scan and by high levels of circulating ACTH. Such liver scans should perhaps be interpreted with caution, and a high blood ACTH level is equally compatible with a secreting tumour or adrenal insufficiency. The positive dexamethazone suppression test done earlier supports this latter hypothesis. It is possible that the undetected abscess had triggered off a brisk pituitary ACTH output as the steroid dosage was inadequate in the face of infection. It is, nevertheless, likely that the primary tumour in the thyroid did secrete ACTH because there were high levels in the tissue, and the adrenal cortex seen histologically was very active.

The deaths in the family have resulted less from thyroid carcinoma than from three classic difficulties of phaeochromocytoma: failure to be aware that a patient may have the condition, an adverse reaction to phentolamine and a septic complication of adrenalectomy. By regular surveillance of members of the next generation every 1 or 2 years these risks to the family should lessen. Apart from clinical features the serum calcitonin and urinary VMA are the variables to be monitored and an abnormally high level of either might be an indication for removal of the appropriate organ. This course is recommended by Melvin et al. (1971) and Miller et al. (1972), who performed thyroidectomy on 11 patients in their kindred with raised serum calcitonin levels and always found medullary carcinoma.

Neoplastic change in duplications of the alimentary tract

M. M. ORR AND A. J. EDWARDS*

SUMMARY

Two cases of adenocarcinoma arising in sequestrated duplications of the bowel in adults are reported. The literature is reviewed and a tendency for duplications to present in early childhood is noted. Although relatively few of these anomalies persist into adult life 8 cases of neoplastic change have now been reported. The histological features of many of the duplications undergoing malignant degeneration suggest the presence of underlying epithelial instability in this condition. It is postulated that duplications of the large bowel have malignant potential.

DUPLICATIONS of the alimentary tract are spherical or tubular congenital anomalies lined by mucous membrane and, typically, well-developed smooth muscle layers. They may arise at any level from the mouth to the anus (Gross et al., 1952) and usually lie in the dorsal mesentery intimately attached to the bowel wall. The rarer tubular variety—under one-third of the total—often communicate with the bowel lumen. The small intestine is the most common segment of bowel involved. Of 242 reported cases (Lo Presti et al., 1949; Gross et al., 1952; Forshall, 1961), 70 per cent involved this site and 14 per cent were at oesophageal level. Duplications of the large bowel are relatively uncommon. However, in 19 exclusively adult cases reviewed by Nolan and Lee (1953) the distribution was more uniform. Generally, duplications produce complications such as intestinal obstruction or haemorrhage requiring surgical treatment in infancy or childhood (Ladd and Gross, 1940; Forshall, 1961), but they may present in adult life as a result of similar complications or as incidental findings at operations or autopsies.

Closed duplications tend to enlarge, as secretions from the mucosal lining accumulate, and cause obstruction of the related loop of bowel or, less commonly, mechanical interference with other structures. They may produce pain purely as a result of increased tension within the cyst, or show the typical clinical features of mesenteric cysts in general. Duplications communicating with the bowel lumen are more often complicated by haemorrhage or perforation, as a result of ischaemia or of peptic ulceration in an area of heterotopic gastric mucosa.

Neoplastic change in a duplication would seem to be a very uncommon event. Few cases have been reported in the literature (Willis, 1967) but most of them concern duplications of the large bowel. These cases have shown few other features in common because of the diversity of form and site displayed by the duplications. The purpose of this paper is to report 2 further cases of this condition and to draw attention to some important considerations regarding its incidence, aetiology and treatment.

Case reports

Case 1: Mrs A. F., a 57-year-old housewife and secretary, presented with a 5-day history of pain in the right lower abdomen, anorexia and mild constipation. The pain was a constant dull ache made worse by eating. There was no history of rectal bleeding or of urinary symptoms. On examination she was mildly pyrexial and there was a tender mass to the right of the umbilicus. The mass was about 10 cm in diameter, hard, rounded and fairly mobile. Pelvic examination was normal.

The patient was admitted immediately for full assessment. The positive findings were a leucocytosis of 15 400/mm^3 with

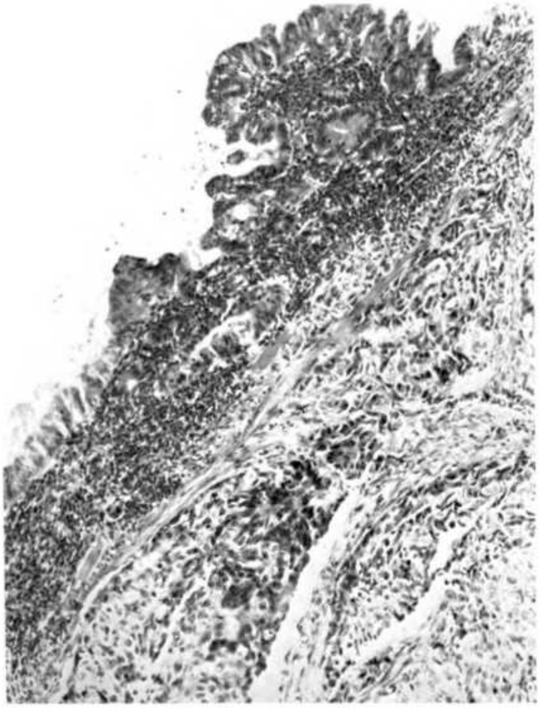

Fig. 4. *Case* 1. Poorly differentiated adenocarcinoma arising from mucous membrane and infiltrating wall of duplication. Note the abnormal epithelium to the left of the frank carcinoma, with cellular atypia and absence of goblet cells. (× 100).

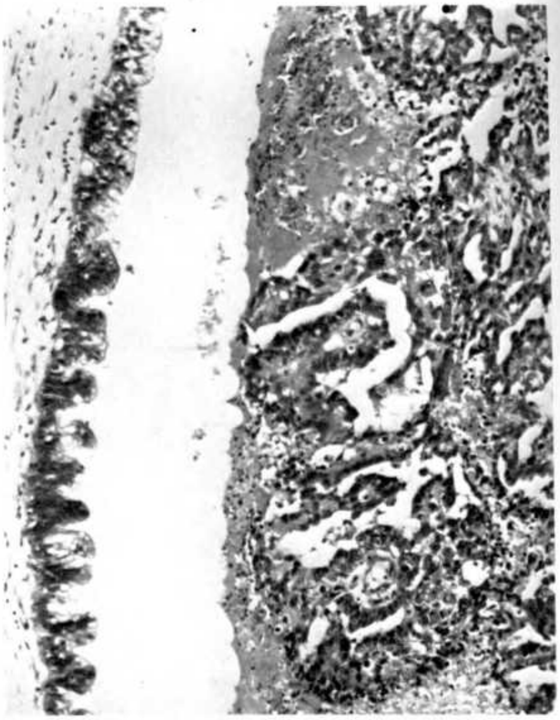

Fig. 5. *Case* 2. Section of mucosal lining of the cystic duplication and moderately differentiated adenocarcinoma within the lumen. The epithelial lining (on the left) shows stratification and cellular atypia. (× 100.)

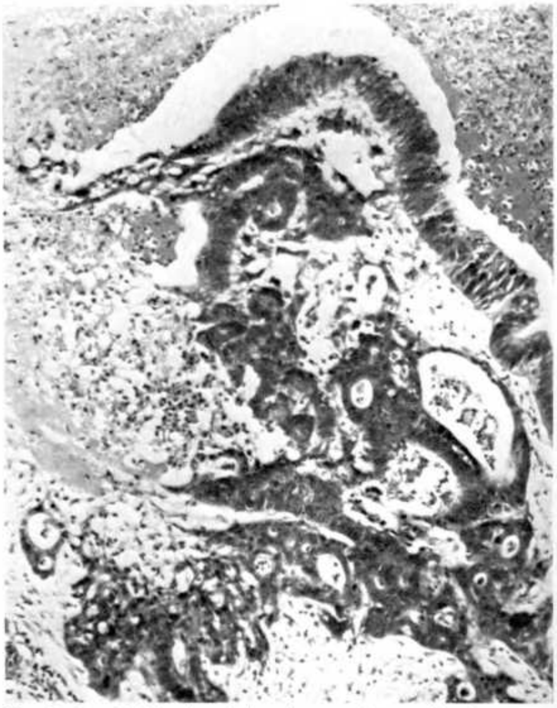

Fig. 6. *Case* 2. Margin of the adenocarcinoma showing infiltration of the cyst wall. Note epithelial atypia present. (× 100).

a marked shift to the left and a slightly raised ESR. Three stools were negative for occult blood, and a chest X-ray, barium enema examination and intravenous pyelogram were all normal.

At laparotomy on 30 October 1972 the hard mass was found to be a chronic abscess in the medial wall of the ascending colon. A limited right hemicolectomy was performed and later histological examination showed that the abscess was due to non-specific perforation of the bowel wall without evidence of tuberculosis, Crohn's disease or neoplasm.

Exploration of the abdomen revealed a sausage-shaped structure, resembling distended small bowel, in the left side of the transverse mesocolon. It was 11 cm long and quite separate from the bowel, although it had a discrete vascular pedicle arising from the root of the superior mesenteric vessels. There was a firm pale nodule 2 cm in diameter in the wall of the tubular structure at its medial end (*Fig.* 1). No enlarged lymph nodes were encountered on mobilizing this apparent duplication, which was excised with its pedicle. The rest of the colon, liver and other viscera were normal.

The patient made an uneventful recovery and has remained well since.

PATHOLOGY: The sausage-shaped structure showed two diverticula on its mesenteric aspect and the whole was filled with brownish mucoid coagulum (*Fig.* 2). Sections confirmed that it was a duplication of the intestine lined by mucus-secreting columnar epithelium and a double-layered smooth muscle coat (*Fig.* 3). The whitish nodule consisted of poorly differentiated adenocarcinoma arising from the mucosal lining of the duplication and there were changes suggestive of carcinoma-in-situ in an extensive field around the frankly neoplastic area (*Fig.* 4). The growth showed penetration through the muscle coat but no evidence of extension outside the wall.

Case 2: Mrs V. S., a 41-year-old postwoman, presented with a 6-week history of pain in the right lower abdomen and backache. The abdominal pain was a constant dull ache, unrelated to eating or other activities, and there were no associated gastro-intestinal symptoms. The only relevant episodes in her medical history were an anterior colporrhaphy 5 months before and an appendicectomy in 1948.

Physical examination revealed a small tender mass in the right iliac fossa, and a subsequent barium enema examination showed this mass to be anteromedial to the ascending colon which was itself normal.

A few days later the patient was admitted urgently with a severe exacerbation of pain in the region of the mass, again with no associated symptoms. On examination she was apyrexial with a normal pulse. There was, however, abdominal tenderness which was maximal over the small mass in the upper right iliac fossa. The mass was 5 cm in diameter, tense and fairly mobile. Pelvic examination was normal. Routine examination of the blood and plain X-rays of the chest and abdomen were normal.

Her pain gradually subsided but the tender mass remained. Laparotomy on 28 October 1968 revealed a rounded cyst adherent to the medial wall of the ascending colon, but with no evidence of inflammation or invasion. There was no other abnormality in the abdomen so the cyst was dissected off the colon and removed without opening the bowel lumen. Full bacteriological examination of the fluid contents of the cyst was negative.

The patient made an uneventful recovery and has remained fit. Two subsequent barium enema examinations showed no abnormality of the colon.

PATHOLOGY: The cyst measured 4 cm in diameter and the wall was up to 2 cm thick with a mainly smooth lining. It contained thick glairy fluid. Sections confirmed the enterogenous nature of the cyst but also revealed an intracystic papillary adenocarcinoma of moderate differentiation. The growth showed invasion of the thin fibrous wall which contained no muscle. The lining of the cyst was varied, with ciliated columnar, cubical and stratified epithelium with atypia adjoining the frankly cancerous epithelium (*Figs.* 5, 6). Calcification beneath the epithelium and in necrotic tumour suggested that the cyst had been present for many years.

Discussion

The literature on the subject of duplications of the alimentary tract is made confusing by the variety of names given to these anomalies by different authors. These include 'reduplication', 'enteric cysts', 'enterogenous cysts', 'giant diverticula', 'ileum duplex', etc. The limitations of some of these terms are obvious and Ladd and Gross (1940) suggested that the term 'duplication' be used for all such anomalies irrespective of their morphology, site or supposed embryological derivation. This would seem to be a satisfactory general term to use, perhaps qualified by other terms where appropriate.

Duplications result from disturbances in embryonic development and various theories have been proposed as to the actual mechanism (Evans and Keith, 1929; Bremer, 1944). There are two main morphological types of duplication—the cystic and the tubular varieties. The classic 'diverticular origin' based on the embryological observations of Lewis and Thyng (1907) might account for the localized cystic type, but some other mechanism must be responsible for the formation of long tubular duplications. Bremer (1944) suggested that they arose from the abnormal persistence of coalescent chains of vacuoles seen in the solid stage of the primitive entodermal tube at about 6 weeks of intra-uterine life. This theory explains the origin of tubular duplications retaining their connection with the bowel lumen at one or both ends, or in the middle, and particularly those which are blind at both ends and entirely separate from the 'parent' tube (with a shared or separate mesentery). *Case* 1 above is an example of the last-named type in which continued secretion had produced a cystic form with two secondary diverticula.

Where vertebral abnormalities coexist with duplications, particularly those involving the foregut, different processes are probably at fault, e.g. the 'split notochord syndrome' and resulting posterior enteric remnants described by Bentley and Smith (1960). Similarly, major duplications of the large bowel associated with doubling of the bladder and genitalia, spina bifida and other major caudal abnormalities must be determined at the blastocyst stage (Ravitch, 1953). Thus, several different embryological maldevelopments may be responsible for different types of duplication.

Occasionally two or more duplications are found in a single patient (Forshall, 1961), and associated anomalies, most commonly malrotation or atresia, are present in a large proportion of cases—31 per cent of those reported by Gross et al. (1952). It has been suggested by Mellish and Koop (1961) that environmental factors such as trauma and hypoxia are likely to be responsible for both the duplications and any associated anomalies.

In tubular duplications the greater part of the wall contains a full complement of normal layers, but in areas of fusion with the bowel the outer layers are shared. The cystic duplication attached to the bowel wall, as in *Case* 2, often lacks a muscular coat as this layer of the 'parent' tube has either been penetrated by

Table 1: DETAILS OF REPORTED CASES OF MALIGNANT CHANGE IN DUPLICATIONS OF THE ALIMENTARY TRACT

* Presentation	Site and type of duplication	Epithelial lining	Neoplasm	Procedure	Course
Gluteal pain, mass per rectum (38; F)*	Presacral; cystic	Mucus-secreting columnar	Adeno.	Excision	Died at 8 mth[1]
Weakness and malaise, anaemia (64; F)	Stomach; cystic	Columnar epithelium, gastric glands	Adeno. (well diff.), node involved	Subtotal gastrectomy	Well at 1 yr[2]
Abdominal pain, weight loss, tender mass (54; M)	Ileum; tubular	Gastric mucosa, epithelial atypia	Adeno. (poorly diff.), nodes, colon and peritoneum involved	Resection	Died at 3 mth[3]
Back pain, mass per rectum (37; F)	Presacral; cystic	Mucus-secreting columnar	Adeno. (moderately well diff.)	Excision	Recurred at 9 mth[4]
Back and abdominal pain, mass (44; F)	Colon; tubular	Columnar and sq. with epithelial atypia	Sq. car. (well diff.), duodenum involved	Right hemicolectomy with duodenal cuff	Died at 6 years of carcinoma of breast. No recurrence[5]
Abdominal pain, tender mass (61 F)	Caecum; tubular	Colonic mucosa, villous adenoma	Adeno. (multifocal well diff.)	Right hemicolectomy	Well[6]
Incidental finding† (57; F)	Mesocolon; tubular	Mucus-secreting columnar, carcinoma-in-situ	Adeno. (poorly diff.)	Excision	Well at 18 mth[7]
Abdominal pain, tender mass‡ (41; F)	Ileocaecal; cystic	Ciliated columnar, cubical, epithelial atypia	Adeno. (moderately well diff.)	Excision	Well at 6 yr[7]

Adeno., adenocarcinoma; diff., differentiated; sq. car., squamous carcinoma.

the diverticulum which produces the cyst or been thinned out by enlargement of the cyst.

The mucosal lining of duplications is very variable in type; it may be identical with the neighbouring bowel mucosa, particularly where a communication exists, or it may imitate any other segment of the alimentary or respiratory tract (Nolan and Lee, 1953). Heterotopic gastric mucosa is commonly found, especially at the dilated blind end of a tubular duplication, and it has even been reported in duplications of the rectum (Gross et al., 1952). Several different types of mucosa may be found within a single anomalous structure, whether cystic or tubular.

Duplications tend to produce symptoms early in life. Forshall (1961) described how cysts in the inner layers of the bowel wall produce obstruction by intussusception, whereas those outside the main muscle tube may cause obstruction of the gut lumen. The commonest complications in her tubular group were perforated peptic ulcer and volvulus. Ladd and Gross (1940) reported many cases of haemorrhage, mucosal ulceration or sloughing on an ischaemic basis due to vessel distortion. Major duplications of the large bowel such as 'double-barrelled colon' generally present in early life as a result of obstruction of one or both channels or faecal fistula (Ravitch, 1953). Prompt surgical intervention in cases of abdominal duplications without associated abnormalities gives a good prognosis.

The incidence of duplications in adult life is unknown as such cases do not lend themselves to collected series. Nolan and Lee (1953) found only 19 cases in the literature and the presentations were similar to those of paediatric cases and included intestinal obstruction and haemorrhage, inferior vena caval compression and incidental findings on chest X-ray. Neoplastic change has not often been described and Willis (1967) mentioned only 2 cases—those reported by Crowley and Page (1960) and by Larizadeh and Powell (1965). Lockwood (1882) described a case of tubular duplication of the descending colon terminating in a mass of malignant disease obstructing the sigmoid colon, but there was no histological confirmation and the site of origin of the tumour could well have been in the sigmoid colon rather than in the duplication.

Ballantyne (1932) reported a case of adenocarcinoma in a presacral enterogenous cyst. He reviewed 4 other cases of adenocarcinoma arising in presacral cysts apparently satisfying the criteria of 'post anal intestine' but one occurred in an infant and one other was not fully documented. He pointed out the possibility that such lesions may be complex congenital tumours with a portion only representing the gut, but there was nothing to suggest teratoma in his case. There have been 2 reports of neoplastic change in duplications lined by gastric mucosa, one concerning an intramural cyst of the stomach itself (Mayo et al., 1955) and the other a tubular duplication of the ileum (Micologhi and Meissner, 1958). More recently, Tamoney and Testa (1967) reported a case of adenocarcinoma arising in a villous adenoma in a short tubular duplication of the caecum.

We have been unable to find any reports of malignant change in duplication cysts in the posterior mediastinum although over 100 such cysts have been recorded (Anderson, 1971). Malignant neoplasms may arise in Meckelian diverticula, but these congenital abnormalities are much more common and they differ both embryologically and morphologically from duplications of the bowel (Moore and Parsons, 1953).

The main feature of 8 well-documented cases of neoplastic change in duplications of the bowel are summarized in *Table I*. Five of the duplications were apparently large bowel derivatives, lined, at least in part, by mucus-secreting columnar epithelium. All but one of the anomalies either communicated with the bowel or were attached to it, the one exception being found within the transverse mesocolon (the present *Case* 1). The predominance of females (7 : 1) is interesting in view of the higher incidence of carcinoma of the colon in the male. All the patients were under 65 years of age and 4 were under 45 years. The presentations have been varied but most patients had pain and only one presented with an unrelated condition. In 6 cases there was a palpable mass which was generally tender.

The histological features of the tumours are unremarkable in that only one was not typical adenocarcinoma of colonic or gastric type; the single squamous carcinoma arose in an area of squamous epithelium probably representing oesophageal mucosa. However, it is noteworthy that the mucosal lining of the duplication in 5 cases showed changes ranging from epithelial atypia to carcinoma-in-situ at the edge of the frank carcinoma. This evidence of epithelial instability suggests a tendency to undergo malignant transformation. In this connection it is clear that ingested but unabsorbed agents or degradation products of normal bowel contents acting as carcinogens cannot be responsible for the lesions in the *sequestrated*, as opposed to communicating, duplications reported here, whatever their place in carcinogenesis in the colon proper (Willis, 1967; Burkitt, 1970). It is, however, possible that some agent normally excreted by the large bowel mucosa may accumulate within a duplication and exert a carcinogenic effect as a result of absolute or relative stasis. The absence of any reports of cases of malignant change in total duplication of the colon treated by a distal re-entry procedure in childhood is consistent with such a mechanism. Whatever the cause it seems clear that duplications of the large bowel are prone to undergo malignant change.

Many of the tumours had reached an advanced stage by the time of presentation and, judging by the mortality in this admittedly small group, the prognosis would seem to be poor. Two patients surviving at 1 year had shown evidence of local spread of the disease at operation. It is not surprising that neoplasms in duplications entirely separate from the alimentary tract should reveal themselves at a later stage than those in the bowel lumen because typical symptoms such as alteration in bowel habit and bleeding per rectum will not occur. The tumour in *Case* 1 had already penetrated the muscle coat when it came to light incidentally, otherwise its presentation might have been long delayed. Barium studies may be non-contributory unless local distortion is produced by the duplication or invading carcinoma. In the absence of a palpable mass, therefore, it may prove very difficult to reach a diagnosis, and even if a tumour is suspected it is rarely that the correct diagnosis is made preoperatively. Duplications communicating with the bowel lumen or within the wall may show up on barium examination and in one case the meoplasm itself has been demonstrated (Tamoney and Testa, 1967).

Once a duplication has been diagnosed it should clearly be removed, even if it is not causing symptoms, because of the risk of future malignant change. In adult cases the possibility of a neoplasm being present should determine a generous clearance of the surrounding tissues and vascular pedicle although this will entail resection of the related loop of bowel.

It is possible that neoplastic change is not such an uncommon complication in the small proportion of duplications that persist into adult life. Indeed the evidence available from the few cases reported, in the incidence both of frank carcinoma and epithelial atypia, suggests that duplication of the large bowel should be classed as a premalignant condition.

Acknowledgements

We are grateful to Mr P. Stringer and Dr J. I. Pugh of St Alban's City Hospital for permission to publish the second case report. We are also indebted to Dr A. G. Stansfield of St Bartholomew's Hospital for reporting on the histology and to Professor R. A. Willis for his interest and advice.

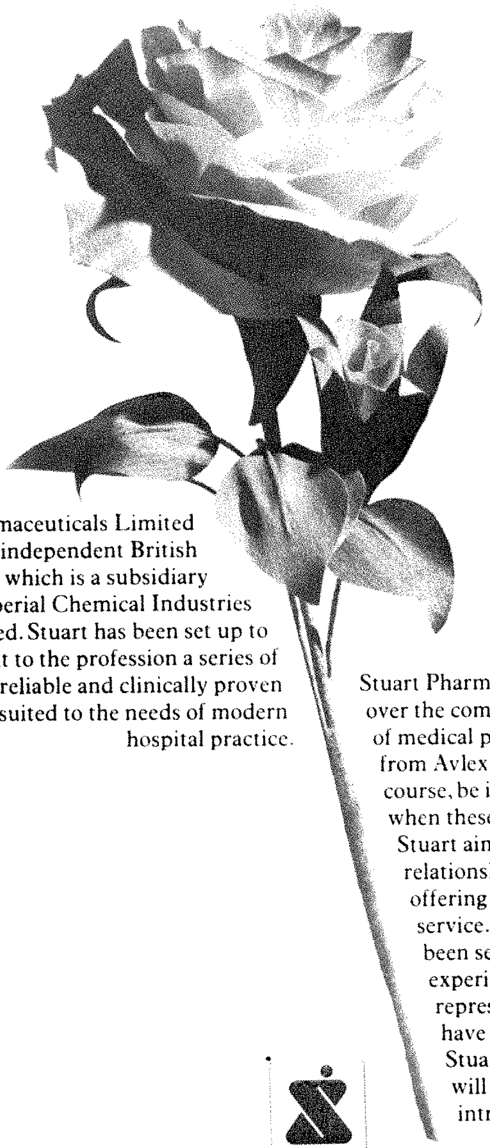
Stuart blossoms



Stuart Pharmaceuticals Limited is a new, independent British Company which is a subsidiary Company of Imperial Chemical Industries Limited. Stuart has been set up to present to the profession a series of reliable and clinically proven products suited to the needs of modern hospital practice.

Stuart Pharmaceuticals will, over the coming year, market a variety of medical products currently available from Avlex Limited. You will, of course, be informed separately as and when these changes occur.

Stuart aims to develop a good working relationship with the profession by offering an efficient and courteous service. To ensure this all staff have been selected for their previous experience and before any Stuart representative calls on you he will have received extensive training in the Stuart range of products. Now if you will kindly turn over the page we will introduce the first of our products.

STUART

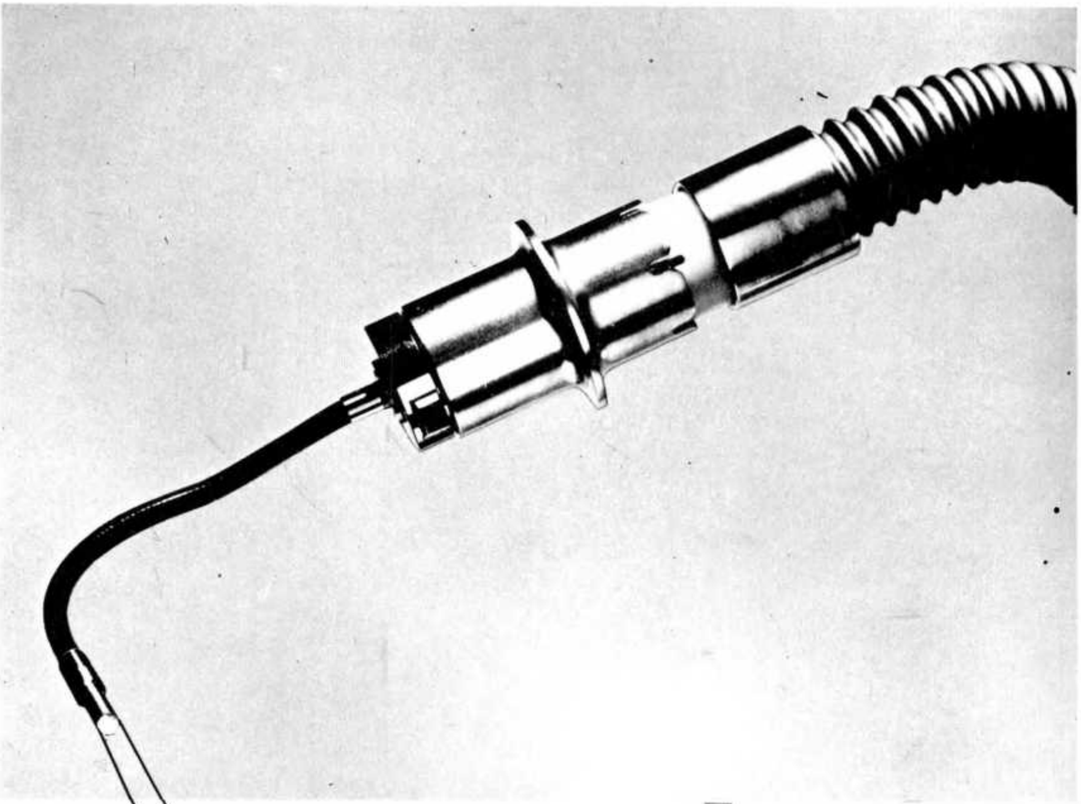
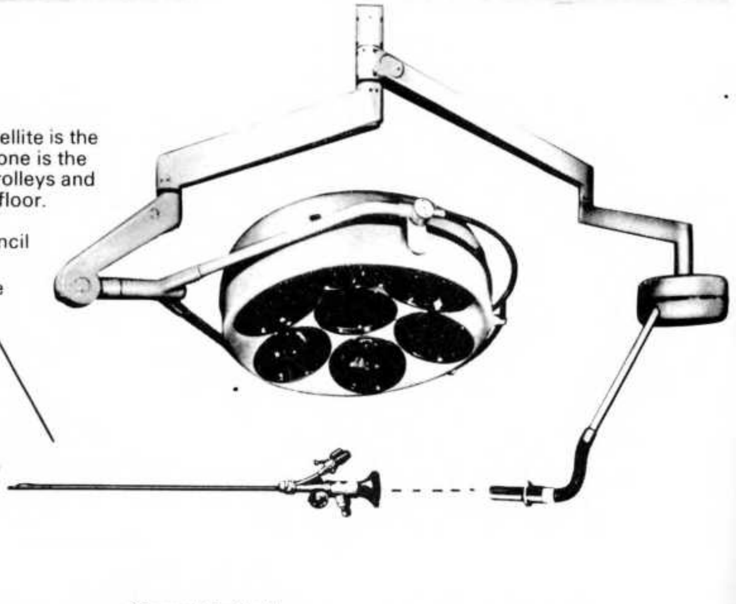
SIEREX

FLEXIBLE PENCIL LIGHT



The Boston lamp with its GFO Satellite is the ideal endoscopic light source. Gone is the need for a separate source, for trolleys and mains cables trailing across the floor.

Illustrated above is a flexible pencil light, ideal for Neuro and ENT surgery, shown connected to the GFO Satellite.



Most glass-fibre endoscopic instruments can be connected in this way.

The pick of the bunch for skin disinfection

'Dispray' 1 Quick Prep.
(formerly known as Hibispray 1)
is an ideal preparation for skin and
hand disinfection in the busy
hospital environment.
At the touch of a button it gives
fast, easy and economical
skin disinfection prior to surgery,
injection or venepuncture.
When colour delineation
is required eg. pre-operatively,
'Dispray' 3 is available
with a red dye.

The 'Dispray' range
combines effectiveness with
convenience and economy.

Instant Availability.
No solutions to prepare.

Easy to use.
No swabs or bottles required.

Quick and Effective.
Rapid bactericidal action.

Efficient Application.
No wasted solutions.

Contents cannot
be contaminated.
No rejected solutions.

Long Lasting.
Contents of one can treat 100 sq. ft.

'Dispray' 1, 2, 3.
The Pick of the Bunch
for Disinfection.

DISPRAY 2

"I Bring Peace"-73

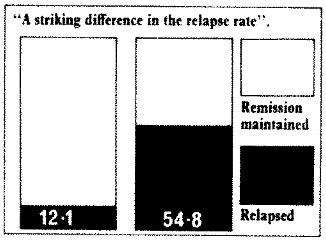
"It is concluded that maintenance treatment of ulcerative colitis with sulphasalazine (salazopyrin) should be continued indefinitely unless contraindicated by side effects".[1]

The results of the above controlled trial carried out at the Nuffield Department of Clinical Medicine, Radcliffe Infirmary, Oxford are all the more welcome as earlier trials of cortisone[2] and prednisone[3] at standard dosages have shown them to be ineffective in reducing the number of recurrences of ulcerative colitis.

"Fortunately, Sulphasalazine tablets, 0.5 grams 4 times a day will prevent relapses in the majority of patients with colitis, and only a few patients cannot tolerate this relatively small dose, which can be continued indefinitely since we do not know when, if ever, it can be safely stopped".[4]

Salazopyrin (sulphasalazine) is available as the plain 0.5g. tablet, 0.5g. EN-tab and as an 0.5g. suppository. Literature and detailed information on Salazopyrin are available on request.

Salazopyrin is a registered trade mark.



"The patients who received dummy tablets had more than four times the relapse rate of those receiving sulphasalazine".[1] (Salazopyrin).

Both groups of patients had been satisfactorily maintained for 1-5 years on Salazopyrin prior to the study, in which they took Salazopyrin or placebo for 6 months.

A controlled trial of parenteral prophylactic gentamicin therapy in biliary surgery

M. R. B. KEIGHLEY, R. M. BADDELEY, D. W. BURDON, J. A. C. EDWARDS,
A. H. QUORAISHI, G. D. OATES, G. T. WATTS AND J. ALEXANDER-WILLIAMS*

SUMMARY

This trial has investigated the value of gentamicin therapy in patients requiring biliary surgery. One hundred consecutive patients were randomly allocated to receive either gentamicin or no antibiotic. Postoperative infection was assessed by an independent observer. Cultures and gentamicin assays were performed on bile and blood sampled during and after operation. The minimum inhibitory concentrations of gentamicin were measured with isolated bacteria.

In 80 per cent of patients biliary organisms were inhibited by 2 μg/ml of gentamicin. Twice this concentration was found in the serum at operation in 88 per cent, but in the bile in only 18 per cent. Nevertheless, gentamicin lowered the incidence of bacteria in the bile from 42 to 25 per cent. There was a reduction in wound sepsis from 21 to 6 per cent ($P < 0{\cdot}05$). Bacteriaemia was demonstrated in only 1 patient receiving gentamicin compared with 5 controls and 1 death occurred from endotoxaemia in the control group.

These data suggest that gentamicin will reduce the morbidity of biliary surgery, particularly in patients in whom the bile is infected at operation.

HIGH colony counts of pathogenic bacteria are found in the bile in a third of patients operated upon for biliary disease (Edlund et al., 1958). The proportion of patients with infected bile is higher in the elderly, in patients with stones in the common bile duct and where emergency operation is considered necessary (Keighley and Graham, 1973). There is a close correlation between the type and presence of bacteria in the bile and the development of postoperative wound sepsis (Robson et al., 1970); also between infected bile and septicaemia (Flemma et al., 1967).

Wound infection is particularly common following biliary surgery (Maxwell et al., 1969). In a prospective study by the Public Health Laboratory Service (Report, 1960) the wound sepsis rate after elective cholecystectomy (20·6 per cent) was similar to that of patients requiring emergency laparotomy for peritonitis. Wound infections complicating gastrointestinal surgery are usually caused by the introduction of endogenous enterobacteria into the incision during operation (Davidson et al., 1971).

Septicaemia is a serious hazard in patients with cholangitis requiring surgical treatment. It is also a complication of diagnostic X-ray procedures involving the injection of contrast material directly into the biliary system (Koch and Gardner, 1969; Williams and Dawson, 1969; Keighley et al., 1974), the main danger being endotoxaemia, which may be complicated by renal failure and which is often fatal (Murdoch et al., 1968). There is a close anatomical relationship between the biliary canaliculi and the liver sinusoids in patients with obstructive jaundice (Edlund and Hanzon, 1953); particles of comparable size to Gram-negative bacteria have been shown to enter the bloodstream from the bile by this route (Huang et al., 1969).

Prophylactic antibiotic therapy will reduce the incidence of postoperative infections, particularly in wounds which become potentially contaminated at operation (Evans and Pollock, 1973). As a result of animal experiments it has been suggested that if antibiotics are to be effective they should be present in the tissues at the time of primary bacterial inoculation (Burke, 1961). In patients requiring biliary surgery the choice of antibiotic will depend upon the sensitivity of the bacteria to various agents and their excretion in the bile. It has been shown, however, that most antibiotics which are commonly found in high concentrations in the bile are inadequately excreted in the presence of obstruction (Schoenfield, 1971). Because most micro-organisms found in the bile are extremely sensitive to gentamicin (Maddocks et al., 1973) and because of the overwhelming importance of avoiding bloodstream infection, gentamicin was chosen for this study.

Materials and methods

One hundred consecutive patients were randomly allocated to a treated group or a control group. Patients receiving gentamicin were given two preoperative 80-mg doses; at 6 a.m. and half-an-hour before leaving the ward for the operating theatre. Although there were occasional delays between the time of the last preoperative dose and operation the interval was never more than 2 hours. This dosage of gentamicin was continued by 8-hourly injections for 5 days after operation.

Exclusion clauses removed from the study any patients where additional surgical procedures (other than appendicectomy or proximal gastric vagotomy) were performed, all cases with malignant obstructive jaundice requiring operation and 1 patient with a previous history of allergy to gentamicin.

The type of abdominal incision, use of subhepatic drains and method of closing a choledochotomy incision were left to the discretion of each surgeon. Drains were used only through a separate wound.

Drain	28	28
No drain	21	20
Site of stones:		
None	1	3
Confined to the gallbladder	37	34
Common bile duct calculi	11	11

At operation samples of bile were aspirated from the gallbladder for culture and viable counts, and when organisms were isolated their sensitivity and the minimum inhibitory concentration of gentamicin were also measured. When operative cholangiography was performed (93 cases) bile was also collected from the common bile duct, where possible before the injection of contrast. Samples of bile and venous blood were collected at operation and stored at 4 °C for batch gentamicin assay.

Wound infection was assessed on alternate days by an independent observer and was recorded only when pus which contained viable organisms was present in the abdominal incision. This was graded into three categories: stitch abscess, superficial sepsis and deep collections of pus. Infection at the drainage site was classified only if bacteria could be cultured from swabs which were collected on the third and fifth days after operation. Blood cultures were taken immediately after the patient returned to the ward, on the third and seventh postoperative days, after T tube cholangiography and in any patient with an unexplained pyrexia after operation. Serum which was taken 1 hour before and 2 hours after injection on the third postoperative day was stored at 4 °C for gentamicin assay at a later date.

Antibiotics were given to the controls or changed in the treated group only when there was bacteriological evidence of severe postoperative infection where specific antibiotic therapy was considered to be essential.

To avoid dangers of dose-dependent nephrotoxicity and damage to the eighth cranial nerve, all patients receiving gentamicin had daily blood urea estimations performed. There were 3 patients in whom the blood urea rose to above 60 mg/100 ml. Gentamicin assays were then performed during treatment and 1 hour before and 1 hour after injection on every other day. The dose of gentamicin was reduced if the peak and trough concentrations were greater than 12 and 8 µg/ml respectively.

Clinical and bacteriological information was recorded on pre-coded work sheets and stored on punch cards. The data have been analysed using a card-sorting machine.

Detailed microbiological investigations

Fresh samples of bile and infected material were cultured under aerobic and anaerobic conditions on blood agar, MacConkey's agar, neomycin-impregnated agar plates and Selenite broth for up to 72 hours. Bacteria were identified by their cultural properties, colonial appearance, motility and biochemical reactions. Organisms were stored on agar slopes or cooked meat broth. Viable counts were measured using tenfold dilutions of 0·1 ml of bile in agar incubated overnight before counting.

The antibiotic sensitivities of bacteria were judged by the zone of inhibition to standard antibiotic-impregnated discs. The minimum inhibitory concentration (MIC) of gentamicin was measured by adding serial dilutions of antibiotic to agar plates which were inoculated with bacteria isolated from the bile and incubated overnight. The concentration of gentamicin which inhibited the growth completely or up to three colonies was taken as the MIC.

Gentamicin assay was performed by the plate diffusion method using *Bacillus subtilis* as the test organism. Wells cut in the agar were filled with serum, bile or standard dilutions at random. Standard gentamicin solutions were prepared by diluting a stock concentration in normal saline, serum, bile or pH buffer. Because there was no appreciable difference in the inhibition zone of the different diluents normal saline was used for making subsequent standards. For each batch of assays a standard curve was made by plotting the gentamicin concentration on a log scale against the diameter of the inhibition zone. The concentration of gentamicin in bile and serum was calculated by measuring the diameter of the clear inhibition zone which was read off from the standard curve. Each estimation was performed in duplicate.

Results

One hundred consecutive patients undergoing biliary surgery were admitted to the trial. There were 3 patients who were withdrawn after completion of the trial. One patient in the treated group had not been given gentamicin before operation, and there were 2 controls who received antibiotics in the immediate postoperative period without bacteriological evidence of an infective complication. Of the remaining 97 cases, 49 received gentamicin and there were 48 controls.

Although the age of the patients differed in the two groups, their clinical presentation, the site of stones and the type of surgical procedures were similar (*Table I*).

There was a reduction in the incidence of bacteria in the bile at operation from 42 per cent in the controls to 25 per cent in the treated group (*Table II*). Despite this there was no obvious difference in the type of organisms in the bile in each group (*Table III*). With the exception of one bile culture, containing a scanty growth of diphtheroids which was considered to be a contaminant, the remainder were all associated with high colony counts of pathogenic bacteria. The only counts which were less than 10^4 organisms per ml were found in 3 patients where samples had been obtained after operative cholangiography.

There was a significant reduction in the wound sepsis rate from 21 per cent in the controls to 6 per cent in the treated group ($P<0\cdot05$) (*Table IV*). Severe wound infection occurred only in the controls. Organisms were isolated from drain site swabs in 14 of the controls, compared with only 3 cases receiving treatment ($P<0\cdot05$). Blood cultures were positive in only 1 patient receiving gentamicin. This occurred, in the absence of clinical infection, 72 hours after cholecystectomy. In contrast, there were 5 patients with clinical signs of bacteriaemia and with positive blood cultures in the early postoperative period in the control group. One of these patients developed endotoxaemia accompanied by renal failure which was responsible for the only operative death in the study.

The incidence of wound sepsis and bacteriaemia was compared in relation to the presence or absence of bacteria in the bile (*Table V*). When the bile was sterile there was a similar incidence of wound sepsis in both the treated and the control groups. However, in patients with infected bile there was a significant reduction in the wound sepsis rate from 40 per cent in the controls to 8 per cent in patients receiving gentamicin ($P<0\cdot05$).

The concentration of gentamicin required to inhibit the growth of organisms isolated in the bile collected at operation or during T tube drainage is shown in *Table VI*. With the exception of bacteroides, *Clostridium welchii* and certain faecal streptococci, all of the remaining organisms were inhibited by 2 µg/ml of gentamicin.

The concentrations of gentamicin in the bile and the serum are shown in *Table VII*. Gentamicin concentrations which were greater than twice the MIC for 85 per cent of biliary micro-organisms (4 µg/ml) were considered to be 'adequate'. Using this figure, 'adequate' concentrations of gentamicin were present in the gallbladder and common bile duct in 18 and 3 per cent of patients respectively. In contrast, satisfactory antibiotic concentrations were found in the serum at operation in 88 per cent of cases. There was also a striking resemblance between the serum gentamicin assays at operation and samples taken 2 hours after injection on the third postoperative day. This suggests that the time interval between the last preoperative injection and removal of the gallbladder rarely exceeded 2 hours. To measure the normal levels of gentamicin in the bile, repeated samples were obtained in 7 patients with T tubes on continual drainage 3 days after operation (*Table VIII*). Only one of these patients had an 'adequate' concentration of gentamicin in the bile 1 hour after injection.

† With one exception organisms isolated in the wound and bloodstream were identical to those in the bile.

Discussion

This study has shown that prophylactic gentamicin given before and for 5 days after operation is associated with a significant reduction in the wound sepsis rate after biliary surgery when the bile is infected. Also infection around the drain site and bacteriaemia were reduced after operation in the treated group.

Bacteria in the bile have previously been shown to be particularly sensitive to gentamicin (Keighley and Graham, 1973; Maddocks et al., 1973). We chose to study gentamicin in the belief that postoperative morbidity is closely related to the presence of Enterobacteriaceae in the bile at operation. As far as we are

aware, the value of gentamicin in patients requiring biliary surgery has not been previously studied.

Because we chose to use a fixed dose of gentamicin it could be argued that some of the patients received insufficient antibiotic for adequate prophylaxis. Nevertheless with only one exception concentrations measured 3 days after operation were within the acceptable range 2 hours after injection.

Gentamicin has been used cautiously in routine prophylaxis because of the dangers of renal impairment and ototoxicity in patients on prolonged therapy or with renal failure. Precautions were taken to prevent this by monitoring serum levels of gentamicin during treatment in patients with an elevated blood urea. Although routine tests of vestibular and auditory function were not performed during this trial there was no clinical evidence of ototoxicity. There were 4 patients with serum gentamicin levels which were greater than 16 μg/ml in the presence of normal renal function. The reason for these extremely high levels has been unexplained.

The aminoglycosides are known to be poorly excreted in the bile. Although there is little information concerning the biliary excretion of gentamicin (Smithivas, 1971) we did not expect to find high concentrations, particularly if there was any degree of biliary obstruction. It has been assumed that high concentrations of antibiotic should be present in the bile if chemotherapy is to be effective in patients undergoing biliary surgery (Twiss et al., 1956; Acocella et al., 1968; Chetlin, 1973). However, the results of this trial have shown that serum antibiotic concentrations were more important than biliary gentamicin levels in reducing postoperative sepsis. The results of serum gentamicin assay demonstrated concentrations of gentamicin which were usually at least two or three times greater than the MIC of all organisms in the bile apart from bacteroides, *Clostridium welchii* and certain faecal streptococci. The relative merits of serum and biliary antibiotic levels as a means of preventing postoperative infection are currently being studied.

Routine prophylactic antibiotic therapy has often been condemned in the majority of patients undergoing elective surgical treatment on the basis that chemotherapy is rarely beneficial and may encourage.

the emergence of resistant bacteria (Altemeier et al., 1956). However, the results of this study have shown that prophylactic gentamicin will reduce the incidence of bacteriaemia and wound infection, particularly when bacteria are present in the bile at the time of operation. For this reason it would seem more logical to advise antibiotic cover only in patients whose biliary tract is liable to be colonized by pathogenic bacteria at operation. We already know that patients with calculous obstructive jaundice are particularly prone to bacteriaemia and that high colony counts of Gram-negative bacteria can be isolated in 90 per cent of these cases (Scott and Khan, 1967). There is also a high incidence of bacteria in the bile in the elderly requiring elective operation and in patients with acute cholecystitis (Watson, 1969). Prophylactic gentamicin therapy should therefore be advised in these patients. We are currently studying the value of an immediate Gram stain on centrifuged bile to detect the presence and type of infecting organism in order that a policy of prophylactic antibiotic therapy given at operation can be adopted. This would be a valuable way of avoiding unnecessary prophylaxis which sooner or later is likely to be associated with resistant organisms and super-infection (Garrod, 1972).

Operative biopsy of the pancreas

PHYLLIS GEORGE, COLIN BROWN AND JAMES GILCHRIST*

SUMMARY

A review has been undertaken of the 47 patients who have had open pancreatic biopsy performed at the Royal Free Hospital between 1967 and 1972. It is concluded that not only is the procedure safe when using the technique described but also it is a valuable and accurate diagnostic procedure.

TAKING biopsies from the pancreas has usually been regarded as a hazardous procedure. For this reason a retrospective study has been undertaken of patients who had open pancreatic biopsies performed during the course of a laparotomy. All the patients were operated on at the Royal Free Hospital between 1967 and 1972 and all were under the care of one surgeon (P. G.). Patients who had transduodenal pancreatic biopsies were excluded from the series. The purpose of this study was to determine whether or not the procedure was safe and whether worthwhile information could be obtained.

Indications

The commonest indication for biopsy (*Cases* 1–35) was to obtain histological confirmation of a suspected carcinoma in patients who had no extrapancreatic spread of the disease but in whom radical surgery had not been undertaken because of the degree of local extension or because of the patient's age or general condition. (Patients who had metastases had the metastatic deposit biopsied and thus were not included in the series.)

Pancreatic biopsies were also taken from patients (*Cases* 36–47) in whom the nature of the pancreatic pathology was in doubt, and also from patients who had preoperative investigations suggesting pancreatic disease but who had a macroscopically normal pancreas at operation. Some illustrative case histories from the latter group are given below.

Case reports

Case 36: A 53-year-old male had a 2-month history of diabetes mellitus and had had one episode of superficial thrombophlebitis in his leg. A barium meal examination was normal but a pancreatic scan suggested a small filling defect in the head of the pancreas.

At laparotomy the gland felt normal. Biopsies were taken from the head, body and tail, all of which showed normal pancreatic tissue. The patient is alive and well 4½ years later.

Case 37: A 48-year-old woman had undergone laparotomy for obstructive jaundice at another hospital when a large mass, thought to be a carcinoma, was found in the head of the pancreas, but no biopsy was taken. A cholecystectomy and choledochojejunostomy were performed and the patient's family was told that she had only a few months to live.

Six months later, when the patient was apparently well, she was referred for a decision as to whether the lesion might be resectable. At operation the pancreas was macroscopically normal, biopsies being taken from the head and body of the gland and also from the para-aortic and mesenteric lymph nodes. All were histologically normal. It was thought that the 'tumour' seen at the original operation probably was a haematoma formed following coeliac axis arteriography. The patient is alive and well 20 months after her second laparotomy.

Case 39: A 43-year-old man complained of anorexia and weight loss. A barium meal and follow through examination showed a widened duodenal loop and an abnormal mucosal pattern at the duodenojejunal flexure.

At laparotomy the pancreas was uniformly thickened, the small and large bowel being macroscopically normal. Three pancreatic biopsies were normal but a full thickness bowel biopsy taken from the duodenojejunal flexure showed lymphoma.

Cases 41, 42 and 43: These patients were explored for obstructive jaundice and found to have biliary calculi and considerable localized thickening of the pancreatic head. There was doubt, macroscopically, as to whether these lesions were areas of chronic pancreatitis or carcinoma, but all the biopsies taken showed chronic pancreatitis. The patients are alive and well 50, 30 and 20 months after operation respectively.

Case 44: A 71-year-old woman was admitted as an emergency with upper abdominal pain and vomiting. On examination she was pyrexial, with tenderness in the epigastrium and right hypochondrium. A plain abdominal X-ray showed gallstones, and her serum amylase was normal. She was diagnosed as having acute cholecystitis, but as her condition did not improve with conservative treatment a laparotomy was performed.

At operation the head of the pancreas was enlarged and oedematous; the gallbladder was full of stones but not inflamed. The common bile duct was not dilated. A cholecystectomy and choledochojejunostomy were performed for a presumed pancreatic carcinoma. However, pancreatic biopsy showed the changes of acute pancreatitis, and the patient is alive and well 4½ years later.

Case 45: A 52-year-old woman with primary biliary cirrhosis was operated on for repeated haematemeses; a large duodenal ulcer was found associated with marked induration in the pancreas, thought to be either carcinoma or reaction to the adjacent ulcer. A biopsy of the affected area of the pancreas showed no evidence of malignancy. The patient died 18 months later of hepatic failure; autopsy confirmed the diagnosis of primary biliary cirrhosis with a normal pancreas.

Case 47: A 51-year-old male underwent laparotomy for recurrent ulceration following a Polya gastrectomy. At operation there was a firm nodule in the body of the pancreas which was thought possibly to be an alpha-cell tumour. This was excised. Histology showed multinucleated giant cells containing birefringent material surrounded by normal pancreatic tissue.

Technique

The anterior surface of the gland is exposed by opening the lesser sac. Inspection and palpation of the head and posterior aspect of the gland can adequately be achieved after incising the posterior parietal peritoneum around the outer edge of the first and second parts of the duodenum; the duodenum and head of the pancreas can then be turned to the left (Kocher's manœuvre).

---

* Departments of Surgery and Histopathology, Royal Free Hospital, London.

The biopsy itself is taken from the most superficial and firmest part of the lesion using a tenotomy knife—a small pyramid (0·3 × 0·3 × 0·3 cm) of tissue is removed. The exposed raw area is covered with either a piece of Oxycel (surgical) or omentum, lightly held in place by two chromic catgut sutures (in the manner of patching a perforated ulcer). A drain is routinely placed in the area and shortened over the subsequent 5 days.

Laboratory diagnosis

All biopsies were treated in the routine manner in the laboratory and stained with haematoxylin and eosin, multiple levels being cut in cases where the diagnosis was not at once apparent. One frozen section was performed and the histology subsequently confirmed on paraffin wax sectioning. On only two occasions was it deemed necessary to request special stains to exclude a rare diagnosis.

Results

Between 1967 and 1972 there were 47 patients who had wedge biopsies of the pancreas. Their ages ranged from 19 to 84 years. The patients are considered in two groups: first those who at operation were thought to have a primary carcinoma of the pancreas (group 1), and secondly those who at operation were thought to have either pancreatic pathology other than carcinoma or a normal pancreas (group 2).

Group 1

There were 35 patients in this group; the average age was 55 years (range 23–84 years).

In 31 patients (88 per cent) the biopsy confirmed the clinical diagnosis. There were 4 patients in whom the biopsy proved inadequate for diagnosis. Two of these patients have since died and autopsy verified the operative diagnosis. The other 2 patients are alive, 12 and 21 months respectively after operation.

All the patients in group 1 had a palliative biliary bypass (usually a choledochojejunostomy with an entero-enterostomy) in addition to the pancreatic

Table I: COMPLICATIONS IN GROUP 1

Case no.	Age	Sex	Complication	Outcome
3	50	F	Biliary fistula	Closed spontaneously
7	64	M	Burst abdomen	Resutured. No further complication
10	64	F	Bronchopneumonia	Recovered
12	70	M	Coronary thrombosis	Died 10 hours post-operatively
18	70	F	Hepatorenal failure	Died 10 days post-operatively
19	81	M	Burst abdomen	Resutured. No further complication
21	62	F	Bronchopneumonia	Died 16 days post-operatively
26	48	F	Gram-negative septicaemia	Died 8 days post-operatively
29	64	F	Infected wound	Delayed wound healing

All these patients had a biliary bypass performed for an inoperable pancreatic carcinoma.

Table II: DETAILS OF PATIENTS IN GROUP 2

Case No.	Age	Sex	Operative diagnosis	Procedure other than pancreatic biopsy	Pancreatic biopsy report	Follow-up
36	53	M	Normal pancreas	None	Normal pancreas	Alive and well after 4½ years
37	48	F	Normal pancreas	Lymph node biopsies	Normal pancreas	Alive and well after 20 months
38	19	M	Solitary pancreatic cyst	Marsupialization of hydatid cyst	Normal pancreas	Alive and well after 9 months
39	43	M	? Chronic pancreatitis	Multiple tissue biopsies	Normal pancreas	Alive and well after 1 year
40	54	M	Chronic pancreatitis	Drainage of cyst	Chronic pancreatitis	Died after 1 month of respiratory failure. No post-mortem
41	57	F	Chronic pancreatitis	Cholecystectomy and exploration of common bile duct	Chronic pancreatitis	Alive and well after 50 months
42	64	F	Chronic pancreatitis	Cholecystectomy and exploration of common bile duct	Chronic pancreatitis	Alive and well after 30 months
43	60	F	Chronic pancreatitis	Cholecystectomy and exploration of common bile duct	Chronic pancreatitis	Alive and well at 20 months
44	71	F	? Acute pancreatitis ? Carcinoma of pancreas	Cholecystectomy and bypass	Acute pancreatitis	Alive and well at 4½ years
45	52	F	? Chronic pancreatitis	Vagotomy and gastro-enterostomy	Normal pancreas	Died after 9 months in liver failure secondary to primary biliary cirrhosis. Post-mortem showed primary biliary cirrhosis and normal pancreas
46	64	M	1. Portal hypertension 2. Mass in body and head of pancreas	Undersewing of gastric varices	Cystadenoma	Died after 2 days of haemorrhage from varices. Post-mortem showed cystadenoma of pancreas
47	51	M	? Alpha cell tumour of pancreas	Vagotomy	Foreign body reaction	Alive and well after 5½ years

biopsy. Nine patients (*Table I*) developed postoperative complications, none of which, however, could be attributed to the biopsy.

Group 2

There were 12 patients in this group (6 males and 6 females). These patients required a variety of operative procedures in addition to having pancreatic biopsy. The operative diagnosis, biopsy report and subsequent follow-up are all summarized in *Table II.*

There were 2 postoperative deaths; one (*Case* 40) died of respiratory failure, and the other (*Case* 46) continued to bleed from his gastric varices. An autopsy in the latter case confirmed that the biopsy was correct.

One other patient (*Case* 45) died 9 months later from hepatic failure. An autopsy confirmed that the pancreas was normal. The other 9 patients are alive and well.

Discussion

With the exception of acute pancreatitis, the nature of pancreatic disease is not always readily diagnosable by the usual investigations. In particular it may be difficult, even at operation, to distinguish between carcinoma and chronic pancreatitis. Pancreatic biopsy seems an obvious step but has usually been regarded as both dangerous and uninformative (Cattell and Warren, 1951).

There are two particular aspects of pancreatic biopsy to be considered: namely whether it is safe, and *only if it is*, is it worthwhile?

Safety

It is generally taught that the pancreas should not be biopsied directly because of the risks of haemorrhage, fistulas, abscess formation, pancreatitis or subphrenic abscess (Moyer et al., 1965; Schultz and Sanders, 1963; Maingot, 1969). For these reasons various authors have advocated that pancreatic biopsies, if they are going to be taken at all, should be taken either transduodenally using a Vim Silverman needle or by excision through the duodenal wall, thus deliberately creating a fistula between the gland and the duodenum (Willbanks and Razzuk, 1971). If the pancreatic lesion involves the lower end of the common bile duct adequate tissue for histological diagnosis may be obtained by curettings taken from within the bile duct (Hall and Krementz, 1968).

The reported complications of pancreatic biopsy have to be evaluated very critically as frequently other surgical procedures are performed at the same time. Forsgren et al. (1968) had only 1 complication in a series of 50 cases that could be attributed to biopsy. Williams et al. (1960) presented a series of 43 cases who underwent a wedge biopsy of the pancreas in addition to having a biliary bypass. These patients were compared with similar number in which only a bypass was performed, and there was no significant difference in either operative morbidity or mortality.

In our series none of the postoperative complications could be attributed to the biopsy. It is felt that the procedure is safe using the technique described, provided that the biopsy can be kept as superficial as possible and care is taken not to biopsy in the region of the main pancreatic duct. If the duct is inadvertently opened then it should be intubated, the tube being brought out to the surface via the stomach, thus producing a pancreaticogastric fistula (Smith, 1972).

Value of biopsy

It is always important to obtain histological confirmation of any pathology for several reasons:

1. The clinical diagnosis may be confirmed or proved incorrect.
2. It may influence subsequent therapy.
3. It may help in giving a more reliable prognosis.
4. It is essential to know the true pathology when comparing different modes of therapy or palliation.

In this series there were 2 patients aged 23 and 24 respectively who had inoperable carcinoma of the pancreas. No matter how 'certain' one may be at operation of the diagnosis, one is still extremely reluctant to make the diagnosis in patients of this age without histological proof. Conversely, *Case* 37 provides an example in which both the patient and her relatives were informed that she had an inoperable carcinoma and had only a few months to live (and she made arrangements for her cremation), when in fact she had a benign lesion.

Any biopsy, and particularly a small one, is subject to two main sources of error, namely: errors of interpretation and errors of sampling. It was possible to review all the histological slides in the series and no errors of interpretation were found. It is the second source of error, namely of sampling, that the critics of pancreatic biopsy emphasize (Bowden, 1954; Schultz and Sanders, 1963).

It is well known that a small pancreatic carcinoma may be surrounded by an extensive area of pancreatitis and this necessarily forms the outermost layer of the tumour, which is the part most readily accessible to the biopsy knife. Hence the carcinoma may not on occasion be biopsied but merely the area of pancreatitis. The incidence of false negatives varies widely in reported series, but figures of 12 per cent or even 54 per cent are quoted (Probstein et al., 1950; Spjut and Ramos, 1957; Cote et al., 1959).

All the patients in our series have been carefully followed up. In group 1 positive biopsies were obtained in 31 out of 35 patients thought to have carcinoma, i.e. in 88 per cent of cases—figures almost identical to those of Williams et al. (1960).

In group 2 only time will show the final accuracy of the biopsies. In the 2 patients who came to autopsy the biopsy report was found to be correct. All the rest of the patients are alive and well, and in particular the 3 patients thought to have chronic pancreatitis have no signs of a carcinoma at 50, 30 and 20 months after operation respectively.

It is concluded that pancreatic biopsy is of value. If carcinoma is found, then there is unequivocal proof of the lesion. If chronic pancreatitis or a normal pancreas is found then there is *contributory* evidence of a non-malignant condition. In the vast majority of cases (91 per cent in this series) worthwhile reliable information will be obtained.

Acknowledgements
We should like to thank Professor Sherlock, who referred the majority of the patients to one of us (P. G.), Professor Ian Bouchier for helpful criticism and Dr P. Scheuer of the Department of Histopathology. We are also grateful to Mrs N. Last and Mrs R. Timings for their secretarial assistance.

Carcinoma of the large bowel in the Sudan

S. H. ELMASRI AND P. B. BOULOS*

SUMMARY

Large bowel cancer is not common but is showing increased frequency in the northern part of the Sudan. It is relatively uncommon among southerners, which may be due to the socio-economic factors prevailing in the Sudan.

The disease affected our population at a younger age than has been generally reported in the literature, and the lesions in nearly 30 per cent were of the mucoid and undifferentiated types.

The incidence in young adults is difficult to explain in the absence of precancerous lesions, and there is not enough evidence to incriminate parasitic infestation.

The incidence of carcinoma of the large bowel has been of great interest to many workers particularly in African countries, where it has been reported to be relatively lower than in affluent societies.

Wynder and Shigematsu (1967) and Burkitt (1971) believed that this relatively low incidence in African countries could be explained on the basis of diet and the socio-economic background of these countries. If this is true, then it would be reasonable to expect a rising incidence of carcinoma of the large bowel in an African community which is progressively moving up the socio-economic ladder and gradually acquiring the dietary habits of Western society.

Materials and methods

We have reviewed the histopathological reports of all specimens of carcinoma of the large bowel received in the Central Research Laboratory, Khartoum, during the period 1963–72. In this laboratory, specimens from all over the country are examined, and accordingly this analysis reflects the overall pattern of this disease in the Sudan.

The results were analysed with regard to annual incidence, sex and age distribution, site of the lesions and their histological appearances.

Results

There were 272 specimens of large bowel cancer; 203 were in the anorectum and 69 in the colon. The sex distribution was 167 males and 105 females, a ratio of roughly 5 : 3. The same ratio was maintained in patients with anorectal cancer and in those with colonic cancer (*Table I*).

The average age for carcinoma of the colon was 44·5 years and that for cancer of the anorectum was 52·3. Of 203 patients with anorectal cancer, 159 (78 per cent) were below the age of 60, while of 69 patents with colonic cancer, 59 (85 per cent) were below this age. Of the whole series, 43 patients were below the age of 30; 34 (16·5 per cent) with anorectal and 9 (14 per cent) with colonic lesions (*Tables II, III*).

The anatomical and histological distributions are shown in *Tables IV* and *V*.

Table I: SEX DISTRIBUTION IN CANCER OF THE COLON AND ANORECTUM

Sex	Colon	Anorectum	Total
Males	42	125	167
Females	27	78	105
Total	69	203	272

Total	42	27	69

Discussion

Unlike many other published series, we have included as large bowel cancer squamous cell carcinoma of the anal canal. In fact, such cancers form a surprisingly high proportion of our series, comprising about one-quarter of the anorectal cancers and about one-fifth of the entire series of large bowel cancers. In the Sudan, therefore, there is a much higher relative incidence of squamous cell cancer of the anal region than is reported from Western countries, for which there is no obvious explanation.

Requests for reprints to S. H. ElMasri, Lecturer in Surgery, Department of Surgery, Faculty of Medicine, PO Box 102, Khartoum, Sudan.

Carcinoma of the large bowel has been described in all age groups. The youngest reported was in a premature infant (Ahfeld, 1880). The youngest in this series was in a boy of 14; 16·5 per cent of our patients with anorectal cancer and 14 per cent with colonic cancer were below the age of 30. These percentages are significantly higher than those reported by other workers, which range between 1 and 9·2 per cent (Recio and Bussey, 1965; Sessions et al., 1965; O'Brien 1967; Miller and Liechty, 1967; Rosato et al., 1969; Gallagher and Michael, 1972).

Van Langenberg and Ong (1972) reviewed a total of 582 cases of large bowel cancer collected since 1961 and found 21 cases (3·6 per cent) in young adults. Their ages ranged between 13 and 25 years. While Goligher (1941) noticed that more than half of his patients with rectal cancer were above the age of 60, 78 per cent of our patients with anorectal cancer and 85 per cent with colonic cancer were below this age.

Why this is so is a matter for speculation. It could be due to the fact that the population at risk in the Sudan is of a younger age group than in other series. The fact that a relatively high proportion of young patients has been affected by large bowel cancer in this series might be associated with the relatively high proportion (29 per cent) of undifferentiated and mucoid types of carcinoma.

Goligher (1967) and Morson (1968) reported an incidence of 25–30 per cent of benign polyps in resected specimens for large bowel cancer. However, precancerous lesions of the large bowel are rare in Africa (Burkitt, 1971; Stewart, 1971). In none of our resected specimens was there any evidence of polyposis, ulcerative colitis or coexisting benign polyps. In only one specimen was there a bilharzial granuloma with ova surrounded by squamous cell carcinoma.

Hickey (1959), reviewing a total of 1337 cases of cancer seen in the Sudan during the period 1935–54 (20 years), found 74 histologically confirmed specimens of large bowel cancer. Seven of these were in the colon while 67 occurred in the anorectum. Lynch et al. (1963), in a similar study of 2234 cases of cancer during the period 1954–61 (8 years), reported 62 cases of cancer of the large bowel, giving an incidence of 2·78 per cent. Twenty-three were in the colon and 39 in the anorectum. In the present analysis (1963–72) the incidence of carcinoma of the large bowel was 4·04 per cent out of a total of 6725 cases of cancer. It appears from these figures that during the latter period there has been a significant increase not only in the total number of cancers detected but also in cancer of the large bowel (*Table VI*). It is tempting to relate this relatively higher incidence of large bowel cancer to factors relevant to the socio-economic development witnessed by this country during the period of the present analysis. Amongst the factors described in the literature to predispose to large bowel cancer is a fibre-depleted diet which delays bowel evacuation and therefore exposes the bowel mucosa to carcinogens for prolonged periods (Burkitt, 1971). It is perhaps relevant at this juncture to note that only 2 cases of large bowel cancer in this series were encountered from the Southern Sudan, where the transit time in the large bowel has been found to be shorter than in a group of subjects in the Northern Sudan (Osman, 1973). However, as there are other differences between the population in Southern and Northern Sudan, we do not feel that it is justifiable to conclude that dietary factors alone are responsible for the increasing incidence of large bowel cancer in the Northern Sudan.

It is quite conceivable that other factors related to socio-economic development might explain this increased incidence of large bowel cancer, e.g. increased detection of cancer due to improvement in health services, health education, etc., in which case this relatively high incidence of large bowel cancer would be an apparent rather than a real one.

Feels right for Septrin

b.d. in urinary infections

When clinical examination reveals urinary infection in children, experience increasingly indicates the need for the prompt, vigorous action of SEPTRIN Paediatric Suspension.

Rated top oral treatment in a British survey of 23,491 urinary pathogen sensitivities,[1] SEPTRIN has been judged superior to ampicillin,[2,3] and is now well established as a first-line treatment for urinary infections.

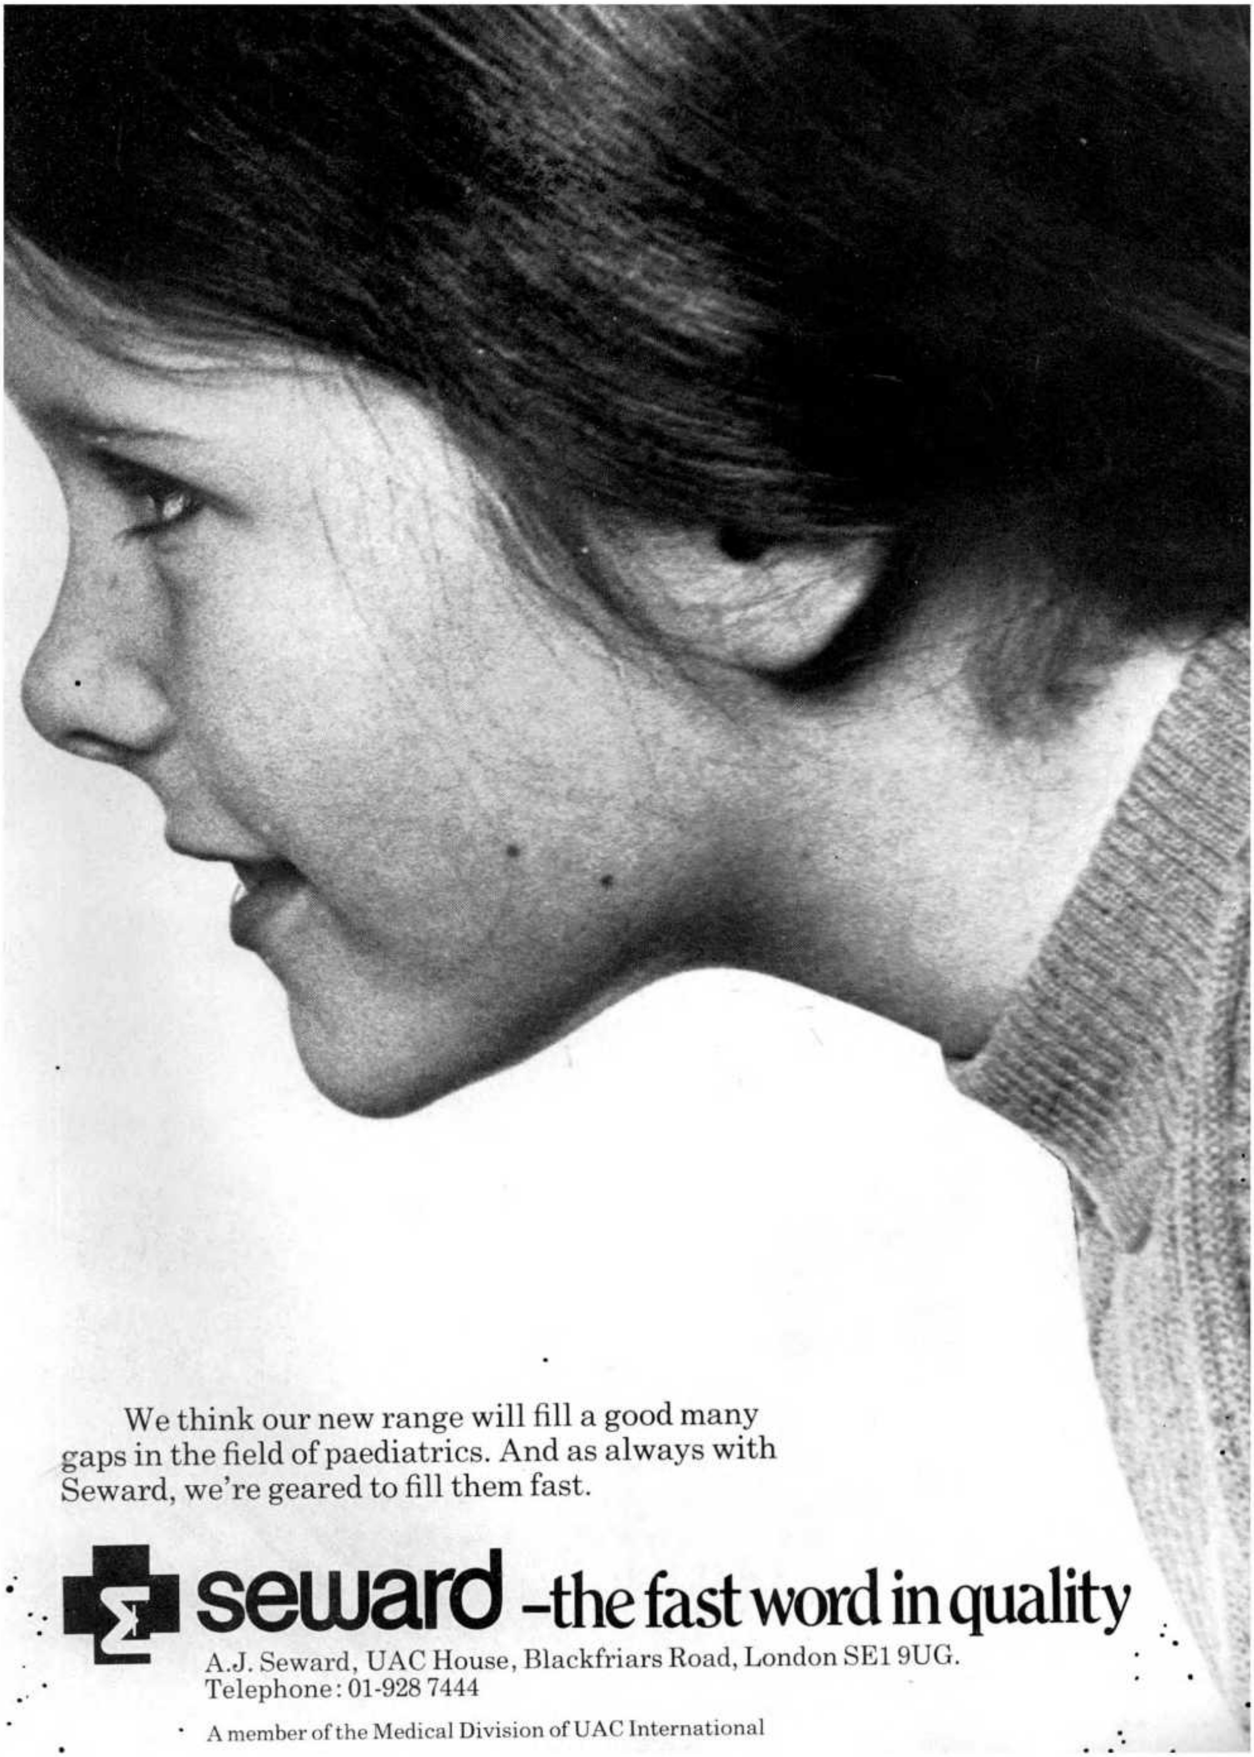
SEPTRIN TRADE MARK
Paediatric Suspension

Now paediatrics gets the Seward treatment.

At Seward, we believe that instruments for paediatric surgery are every bit as important as adult instruments.

That's why we spent a long time developing and perfecting our own paediatric range – and we're grateful for the co-operation of so many children's hospitals, paediatric departments and consultants.

Now the range is complete – 580 fine quality stainless steel instruments. Including many which have never before been modified for paediatric use. And some entirely new instruments developed in the Seward workshop.



We think our new range will fill a good many gaps in the field of paediatrics. And as always with Seward, we're geared to fill them fast.

seward –the fast word in quality

A controlled clinical trial of three different methods of perineal wound management following excision of the rectum

T. T. IRVIN AND J. C. GOLIGHER

SUMMARY

Three methods of perineal wound closure were studied in a randomized prospective clinical trial in 106 patients undergoing excision of the rectum for inflammatory or malignant disease. In method 1 the perineal wound was managed by open drainage. In both methods 2 and 3 the perineal wound was closed by primary suture, suprapubic suction drains being left down to the presacral space, but in method 2 the pelvic peritoneal floor was reconstituted, whilst in method 3 it was left unsutured. Topical and systemic antibiotics were administered to all patients submitted to primary closure of the perineal wound but not routinely to those whose perineal wound was left open.

The overall operative mortality was 8·5 per cent but no deaths could be definitely attributed to perineal wound complications. The incidence of primary wound healing after methods 2 and 3 was 45·2 and 42·9 per cent respectively. Operative contamination of the perineal wound had an adverse effect on perineal wound healing. The incidence of persistent wound sinuses and unhealed wounds at 3 and 6 months after primary wound closure was rather less than that encountered after open drainage.

It was concluded that primary closure of the perineal wound is the treatment of choice following excision of the rectum, except in cases in which contamination of the perineal wound has occurred during operation or the final state of haemostasis in the pelvis with diathermy and suture at the conclusion of the dissection was deemed to be unsatisfactory.

One of the major sources of discomfort and concern to patients who have undergone excision of the rectum is the perineal wound. Traditionally this wound is left partly open and packed (Miles, 1908, 1926), or only partially closed around a wound drain (Gabriel, 1963). In either event the wound must be regularly irrigated and partly repacked during the postoperative period, and several uncomfortable weeks or months may elapse before healing is complete.

Recently, it has been suggested that primary suture of the perineal wound may obviate much of the inconvenience of the traditionally managed perineal wound after rectal excision and may be followed by primary healing in a significant proportion of cases (Oates and Alexander-Williams, 1970; Hultén et al., 1971; Altemeier et al., 1974; Broader et al., 1974). The failures recorded after primary suture have been due to abscess or haematoma formation in the presacral space below the pelvic peritoneum, and Ruckley et al. (1970) attempted to overcome this problem by incorporating a pedicled omental graft in the dead space below the pelvic peritoneal floor. Another simple method which various surgeons (e.g. Haxton, 1970) have used in the past in an effort to overcome the problem of the presacral dead space is to avoid suturing the pelvic peritoneum altogether, thus permitting the small intestine to occupy the pelvic cavity.

However, we have been unable to discover any strictly objective published data on the relative merits of these different modifications of technique and have thus been prompted to institute a prospective randomized properly controlled clinical trial of two different methods of primary closure of the perineal wound against the traditional method of open drainage.

Materials and methods

Methods of perineal wound management on trial

The three methods being tried were:

Method 1. *Open drainage*: The pelvic peritoneum was sutured with a running catgut suture, and the perineal wound was partially closed with interrupted silk skin sutures. The middle third of the wound was left open around a corrugated rubber drain which drained the presacral space.

The drain was removed on the third postoperative day, and thereafter the wound was irrigated daily with a solution of hydrogen peroxide and loosely packed with gauze soaked in a 2·5 per cent solution of Milton.

Method 2. *Primary suture of perineum and pelvic peritoneum*: Two small suprapubic suction drains with multiple perforations were brought out extraperitoneally from the presacral space, and the pelvic peritoneum was closed with a running catgut suture. The presacral space was sprayed with a polymyxin–bacitracin aerosol, and the perineal wound was closed. Suture of the levator muscles was usually impossible, but the ischiorectal fat was approximated with interrupted chromic catgut sutures, and the perineal skin was closed with interrupted silk sutures. The suction drains were attached to rechargeable vacuum bottles after the abdomen was closed.

Method 3. *Primary suture of perineum and non-suture of pelvic peritoneum*: The pelvic peritoneum was not closed but, as in method 2, two small suprapubic suction drains were brought out from the presacral space. The perineal wound was closed in the same way as

method 2 cases after spraying the presacral space with a polymyxin–bacitracin aerosol.

The patients treated by methods 2 and 3 were given ampicillin by intramuscular injection for 5 days after surgery. The suction drains were removed when they ceased to drain significant amounts of blood or serum, which was usually on the fourth or fifth postoperative day, and the perineal skin sutures were removed on the eighth postoperative day.

Allocation of patients to the trial

During the period of the study all patients undergoing rectal excision in the Professorial Surgical Unit, either as a separate operation or as part of a proctocolectomy, were considered for inclusion in the trial, but approximately two-fifths of them were rejected for three reasons.

a. In female patients having abdominoperineal excision for rectal cancer it was our invariable practice to excise the posterior vaginal wall along with the rectum. Because of the inability to provide a complete closure of the pelvic cavity from below after sacrificing the posterior vaginal wall, such patients were not included in the trial, two options of which would involve closure in this way. Instead patients from whom the posterior vaginal wall was removed with the rectum were treated electively by suture of the posterior three-quarters of the perineal wound, the pelvic cavity being drained by a strip of corrugated rubber inserted through the vaginal introitus and through the gap where the posterior vaginal wall had been.

b. If at the conclusion of the operation complete haemostasis in the pelvis could not be achieved by diathermy, ligature or suture, packing of the perineal wound with a gauze roll was necessary and the case was not entered in the trial.

c. If there had been *gross* contamination of the perineal wound during operation from associated fistulation or from laceration of the rectum during its removal, open drainage was preferred, rendering the case ineligible for incorporation in the trial.

Results

Numbers of patients included and allocation to the three methods

Altogether 106 patients were included in the trial; 57 treated by abdominoperineal excision of the rectum alone and 49 by proctocolectomy, the indications for the operations being carcinoma in 48 cases, ulcerative colitis in 37 cases and Crohn's disease in 21 cases.

The allocation of cases to the three methods of perineal wound management was 29 to method 1, 33 to method 2 and 44 to method 3.

Operative mortality

The overall operative mortality in the study was 8·5 per cent, but none of the 9 deaths could be definitely attributed to perineal wound complications.

Five patients died after method 1: 2 of advanced malignant disease, 2 of cardiorespiratory complications and the fifth of unexplained peritoneal sepsis and an intraperitoneal haemorrhage possibly related to systemic steroid therapy.

Two patients died after method 2: one from a massive pulmonary embolism and the other from a cerebrovascular accident.

Two patients died after method 3: both from peritonitis, in one case the result of colostomy necrosis and in the other from an unexplained perforation of the ileum. It is conceivable that the intraperitoneal drain used in the latter case may have caused pressure necrosis of the ileum.

Similarity of the groups of patients treated by the three methods

Excluding the 9 patients who succumbed during the early postoperative period, the numbers of patients available for study were 24 in method 1, 31 in method 2 and 42 in method 3.

Table I compares these groups with regard to age, sex, the incidence of systemic steroid therapy and operative contamination of the perineal wound, the nature of the initial disease and the type of operation performed. All the patients who were receiving systemic steroids and those who had received steroids within the 3 months prior to operation were given steroid cover during and after the operation.

It can be seen that there were some differences between the three groups with regard to several of these clinical variables. There were fewer females and more cases of Crohn's disease in method 1, and the incidence of systemic steroid therapy and operative contamination of the perineal wound was rather less in method 3 than in the other two methods. However, none of the differences between the three methods is statistically significant.

Perineal wound healing
Table II shows the data on the healing of the perineal wounds in the three groups of patients. It can be seen that there was no significant difference between the results obtained with the two methods of primary suture. Primary healing of the perineal wound occurred in 45·2 per cent of the patients in method 2 (suture of the perineum and pelvic peritoneum) and in 42·9 per cent of the patients in method 3 (suture of the perineum and non-suture of the pelvic peritoneum).

The results at 3 and 6 months respectively after operation showed that perineal wound healing was delayed in the open drainage method (method 1) compared with both methods managed by primary suture. Complete healing of the perineal wound at 3 months had occurred in only 30 per cent of the patients in method 1, whereas two-thirds of the wounds in methods 2 and 3 had healed by this time. Similarly, at 6 months healing had occurred in only 65 per cent of the wounds in method 1, whereas more than 80 per cent of the wounds in methods 2 and 3 had healed. However, these differences between the perineal wounds in method 1 and in methods 2 and 3 just fail to achieve statistical significance. Two patients are not included in the results at 3 and 6 months. One patient in method 3 had died of metastases and a patient in method 1 defaulted from the outpatients' clinic.

Morbidity
Table III shows the mean duration of stay in hospital for the patients in the three groups, and the incidence of postoperative ileus or intestinal obstruction and of further operations on the perineal wound.

The duration of stay in hospital was similar for each group and amounted to almost 4 weeks. Similarly, there was no significant difference between the three groups with regard to the incidence of ileus or obstruction, or further operations on the perineal wound.

For the purpose of the study, ileus was diagnosed if the patient failed to pass flatus or faeces by the fifth postoperative day, and intestinal obstruction was recorded when intestinal colic and vomiting required intravenous fluids and the cessation of oral intake. Approximately 20–30 per cent of patients developed ileus or obstruction according to these criteria, but no patient required a further laparotomy for these complications. The absence of a sutured pelvic peritoneum in method 3 patients did not result in a significant increase in the incidence of ileus or obstructive complications.

In method 1, 5 patients (20·8 per cent) required further operations on the perineal wound. In 3 cases the wound had to be packed within several hours of the original operation because of persistent bleeding, and 2 cases required exploration of the perineal wound for secondary haemorrhage during the second postoperative week. In method 2, 8 patients (25·8 per cent) developed a haematoma or abscess in the presacral space, and they required further surgical intervention. Similarly, 8 patients (19·0 per cent) in method 3 underwent further operations for septic complications in the perineal wound.

Table III: MEAN DURATION OF HOSPITAL STAY, INCIDENCE OF POSTOPERATIVE ILEUS OR INTESTINAL OBSTRUCTION AND FREQUENCY OF FURTHER OPERATIONS ON THE PERINEAL WOUND

	Method 1		Method 2		Method 3	
	No.	%	No.	%	No.	%
Average duration of stay in hospital (days ± s.e.)	27·6 ±2·23		27·4 ±1·95		27·7 ±1·51	
No. of cases of post-operative intestinal obstruction or ileus	6	25·0	6	19·4	12	28·6
No. of cases requiring further operations on the perineal wound	5	20·8	8	25·9	8	19·0

One patient in each of the two methods managed by primary suture of the perineal wound became seriously ill as a result of pelvic sepsis:

Case report (*method* 2): A 34-year-old female underwent proctocolectomy for ulcerative colitis. The operation was complicated by contamination of the perineal wound and the patient was receiving systemic steroids. On the third postoperative day she developed a swinging pyrexia, jaundice, thrombocytopenia and some degree of circulatory collapse. Inspection of the perineal wound revealed no external abnormality, and there was very little drainage from the presacral suction drains. Despite the normal appearance of the perineal wound it was felt that infection in the presacral space was the most likely explanation for the clinical features.

The patient was resuscitated and the perineal wound was explored. A large infected haematoma was evacuated from the space below the pelvic peritoneum. Her postoperative course was stormy, and a consumptive coagulopathy persisted for several days, but she went on to make a satisfactory recovery.

Case report (*method* 3): A 56-year-old woman underwent a rectal excision for ulcerative colitis. On the third postoperative day she developed spreading abdominal tenderness and vomiting, and examination revealed signs of peritonitis, maximal in the right iliac fossa. Inspection of the perineal wound revealed no external abnormality and there was little drainage from the presacral suction drains.

Laparotomy was performed and she was found to have a lower abdominal peritonitis with pus in the presacral space. The perineal wound was opened and packed, and she went on to make a satisfactory recovery, although ileus persisted for 10 days after surgery.

Factors affecting primary wound healing
Table IV shows the relationship between primary healing of the perineal wound and systemic steroid therapy, the nature of the underlying disease and operative contamination of the perineal wound. It can be seen that the only factor which had any significant bearing on the healing of wounds closed by primary suture was operative contamination of the wound. Contamination of the perineal wound with pus or faeces occurred in 9 cases, and none of these patients achieved primary wound healing. The difference between the healing of contaminated and uncontaminated perineal wounds is statistically significant ($\chi^2 = 4{\cdot}50$, $P < 0{\cdot}05$).

Table IV: RELATIONSHIP BETWEEN PRIMARY WOUND HEALING AND SYSTEMIC STEROID THERAPY, NATURE OF THE PRIMARY DISEASE AND OPERATIVE CONTAMINATION OF THE WOUND

	No. of cases	Healed *per primam*	% Primary healing
Systemic steroid therapy	24	10	41·7
No steroids	49	22	44·9
Nature of primary disease:			
Carcinoma	33	15	45·5
Ulcerative colitis	29	13	44·8
Crohn's disease	11	4	36·4
Operative contamination of perineal wound	9	0	0*
No contamination of perineal wound	64	32	50·0

* Significant incidence of failure in contaminated wounds ($\chi^2 = 4{\cdot}50$, $P \leq 0{\cdot}05$).

Table V: RELATIONSHIP BETWEEN UNHEALED WOUNDS AT 6 MONTHS AFTER SURGERY AND NATURE OF THE ORIGINAL DISEASE

Primary disease	No. of wounds unhealed	% Unhealed
Carcinoma	4	9·3
Ulcerative colitis	10	30·3*
Crohn's disease	7	36·8†

* Incidence of unhealed wounds in cases of ulcerative colitis significantly greater than that in carcinoma cases ($\chi^2 = 4{\cdot}47$, $P < 0{\cdot}05$).

† Incidence of unhealed wounds in cases of Crohn's disease significantly greater than that in carcinoma cases ($\chi^25 = \cdot63$, $P < 0{\cdot}02$).

Delayed wound healing

The total incidence of unhealed perineal wounds and persisting wound sinuses at 6 months after surgery was 22 per cent. *Table V* shows the relationship between this complication and the nature of the original disease. It can be seen that unhealed perineal wounds were significantly less common after operations for carcinoma by comparison with operations for Crohn's disease ($\chi^2 = 5{\cdot}63$, $P < 0{\cdot}02$) or ulcerative colitis ($\chi^2 = 4{\cdot}47$, $P < 0{\cdot}05$).

Discussion

In recent years a number of surgeons have recommended that the perineal wound following rectal excision should be closed by primary suture. Hultén et al. (1971), in a study of 36 patients managed by primary closure of the perineal wound, found that primary healing occurred in 75 per cent. Broader et al. (1974) reported that primary healing occurred in 63 per cent of 106 patients given primary closure, and Altemeier et al. (1974) claimed healing *per primam* in no less than 92 per cent of 125 patients with rectal cancer similarly managed. In the present study 44 per cent of primarily closed wounds healed by first intention.

The failures which have been recorded after primary closure of the perineal wound have been due to haematoma or abscess formation in the presacral space below the pelvic peritoneum (Hultén et al., 1971; Broader et al., 1974), and this was also our experience in the present study. It might have been expected that such troubles would be to a large extent avoided by th tion drainage to this site instituted by these three groups of workers and by ourselves, but presur the removal of blood from this space by sucti often less efficient than could be desired, partic if there is delay in commencing the suction at the clusion of the perineal dissection. We had cauti hoped that a further useful contribution to the sol of this problem might be provided by leaving th vic peritoneum unsutured in method 3, thus perm the small intestine to fall down into the pelvic and obliterate the presacral dead space. Howeve incidence of primary wound healing in the gro patients managed in this way in the present stud not significantly different from that which obt in the group in which the pelvic peritoneum sutured (*Table II*). Fortunately, the absence pelvic peritoneum did not result in an increase dence of postoperative obstructive complicatio ileus, but this method has the potential disadva that it may permit any sepsis arising in the pre space to spread upwards into the general perit cavity, as occurred in one case in the present On balance, therefore, we see no advantage in le the pelvic peritoneum unsutured.

Ruckley et al. (1970) described a method of pr closure of the perineal wound which incorpora pedicled graft of omentum in the space belo pelvic peritoneum, and they found that 8 out cases managed in this way achieved complete h of the perineal wound within 3 weeks of surger have no experience of this method but the reported by Ruckley et al. do not appear significantly better than those observed in the p study.

Another plan for dealing with the presacral sp connection with primary suture of the perineal would be to arrange for its periodic or constant tion as well as for suction, preferably using some tion, such as hyaluronidase or even streptokinas could help to dissolve any clot that might have fo We have so far had only minimal experience wi régime but we note that Schwab and Kelly (1974 used something similar with encouraging results

Several aspects were investigated in the p study in an effort to detect any systemic or local f which might adversely affect primary healing perineal wound. The use of systemic steroids cou be correlated with an increased incidence of w breakdown, nor was there any apparent corre between primary wound healing and the nature initial disease. However, there was a signifi higher incidence of failure in primarily closed w when operative contamination had occurred. tamination occurred in 9 of the wounds in our managed by primary closure, and none heale *primam*. Broader et al. (1974) also found that ope contamination had an adverse effect on the heal primarily closed wounds—in their study conta tion occurred in 15 wounds and only 5 of these *per primam*. These authors felt that primary clos contaminated perineal wounds was still indi presumably on the basis that no serious harm would result even if sepsis should occur, but we would strongly recommend that primary closure should not be performed if contamination of the perineal wound has taken place. In our experience primary wound healing is never achieved under these circumstances, and we have had one case in which serious septic complications ensued following primary closure of a contaminated perineal wound.

The average stay in hospital for the groups of patients managed by primary suture of the perineal wound was not significantly different from that of the group managed by open drainage. This similarity is not explained by a lengthy convalescence on the part of patients who required further operations on primarily closed wounds. Indeed, the need for further operations on the perineal wound did not seem to have any significant effect on the duration of stay. It appears that the duration of the period in hospital is principally related to the speed with which the patient attains the necessary confidence in the care of the ileostomy or colostomy. Thus, the average stay in hospital for the patients in all groups in the present study was about 4 weeks, irrespective of the methods used to manage the perineal wound.

Delayed healing of the perineal wound and persistent wound sinuses are troublesome complications which affect a significant proportion of patients following rectal excision. It is widely held that these complications are more common after operations for inflammatory diseases of the colon than after operations for carcinoma. In a study of 93 cases of ulcerative colitis treated by proctocolectomy, Watts et al. (1966) found that the incidence of unhealed wounds 6 months later was 25 per cent, and Jalan et al. (1969) recorded that the incidence of unhealed wounds in 106 cases of ulcerative colitis at 6 months after radical operation was 55 per cent. Lockhart-Mummery and Morson (1960) also stated that delayed healing of the perineal wound was a significant problem following rectal excisions for Crohn's disease, and Broader et al. (1974) found that the incidence of perineal sinuses 1 year after rectal excisions was four times greater in cases of Crohn's disease and ulcerative colitis than in cases of rectal carcinoma.

The present study has confirmed that perineal sinuses and unhealed perineal wounds are significantly more common after operations for Crohn's disease and ulcerative colitis compared with operations for carcinoma (*Table V*), but it was gratifying to find that the methods of primary wound closure used in the present study did not compound this problem. Indeed, persisting perineal sinuses were less commonly found in cases managed by primary suture of the perineal wound than in cases managed by open drainage.

It appears, therefore, that primary wound closure can be recommended as the most suitable management of the perineal wound following rectal excision, except for cases in which haemostasis in the pelvis has been incomplete or operative contamination has occurred. In our experience rather less than half the cases managed in this way heal *per primam*, but the wound complications which arise in the remainder are rarely of serious significance and convalescence is seldom prolonged. Furthermore, the subsequent healing of the perineal wound does not seem to be adversely affected when primary suture fails, and the incidence of persisting perineal sinuses and unhealed wounds in cases managed by primary wound closure is less than that which is encountered in cases treated by open drainage.

Povidone-iodine for the control of surgical wound infection: a controlled clinical trial against topical cephaloridine

A. V. POLLOCK AND MARY EVANS*

SUMMARY

One hundred and ninety-two operation wounds in a general surgical practice were randomly allocated to receive either topical cephaloridine or a povidone-iodine spray, and the rate of wound sepsis was studied. In all types of operation cephaloridine proved superior to povidone-iodine as a prophylactic, the difference reaching a significant level in potentially contaminated wounds.

SEPSIS in a sutured surgical wound can cause suffering, economic hardship and, occasionally, serious illness or even death. Many methods have been advocated for the reduction of the rate of surgical wound infection and among these the application of topical antibiotics at the time of operation has stood the test of numerous controlled clinical trials (Evans et al., 1974).

Polk and Lopez-Mayor (1969), however, reported a significant lowering of their surgical wound sepsis rate by three doses of cephaloridine administered not topically but parenterally, and this work has been confirmed (Evans and Pollock, 1973).

Approaching the problem from a different direction, Gilmore and Martin (1974) have reported a significant reduction in the rate of sepsis in gridiron incisions for appendicectomy by a non-antibiotic application, namely povidone-iodine.

There is, naturally, a reluctance to use valuable therapeutic antibiotics for wound infection control because of the possibility of encouraging the emergence of resistant strains (Garrod, 1972). We have, therefore, tested in a randomly controlled clinical trial in a general surgical practice a povidone-iodine spray against topically applied cephaloridine, which has already been proved to be an effective prophylactic (Evans et al., 1974).

Patients and methods

Two hundred and six consecutive sutured surgical wounds (excluding wounds less than 3 cm in length and perineal wounds for abdominoperineal excisions of the rectum) were studied. The allocation to povidone-iodine spray or control (cephaloridine) was by the toss of a coin, and all the wounds were observed for at least 1 month. Fourteen patients who either received preoperative antibiotics or died within 4 weeks of operation without wound infection were excluded from the trial, leaving 192 wounds for analysis.

Povidone-iodine (Disadine DP, Avlex Ltd) is supplied as a dry powder in an aerosol can. It was sprayed into the wound during closure from a distance of 25 cm for 8 seconds. After the skin had been sutured the wound edges were again sprayed in the same way.

For the controls 1 g of cephaloridine (Ceporin, Glaxo Laboratories Ltd) was dissolved in 2 ml of water and instilled into the wound before skin closure, with care to avoid spillage.

In the majority of the potentially contaminated wounds a swab from the opened viscus or the infected lesion was sent for bacteriological examination, including cephaloridine sensitivity. Pus from most discharging wounds was cultured and the sensitivity of the organisms to cephaloridine determined.

In order to avoid observer bias the method of prophylaxis used was recorded on punch cards separate from the patient's notes. The significance of differences was assessed by calculation of χ^2.

Definitions

Primary wound sepsis is defined as 'a clear collection of pus which empties itself spontaneously or after incision' (Ljungqvist, 1964) and secondary sepsis as 'that which follows discharge from the wound of a substance other than pus' (Pollock, 1973). We recognize that it is possible for a wound discharging pus (and therefore primarily infected) to acquire a secondary infection as well, but this has not altered the classification of that infection as primary.

A wound which discharged fluid within 4 weeks of operation was regarded as septic unless the discharge was merely of serum or lymph, was sterile and rapidly ceased. Although some wound swabs were reported to be sterile, if the discharge was obviously pus the wound was classified 'septic'.

We have classified wounds as 'clean' (in which there is no likelihood of endogenous bacterial contamination) and 'potentially contaminated' (in which this exists to a greater or lesser degree—we have recognized once again the higher incidence of wound sepsis with colorectal surgery including perforated appendicitis).

Results

One hundred and ninety-two wounds were studied. Eighty-six received cephaloridine and 106 povidone-iodine spray.

Primary infections

Four wounds discharged pus in the cephaloridine group (5·1 per cent) and 19 in the povidone-iodine group (17·9 per cent). Both in clean and in potentially

Table I: COMPARISON OF WOUND INFECTIONS IN THE CEPHALORIDINE AND POVIDONE-IODINE GROUPS

	Cephaloridine			Povidone-iodine		
	Total wounds	Primary sepsis	Secondary sepsis	Total wounds	Primary sepsis	Secondary sepsis
Clean						
Head and neck	2	0	0	6	0	1
Breast and axilla	4	0	1	4	0	1
Laparotomy	7	0	0	5	1	0
Lumbar	4	0	0	5	0	0
Groin hernias and varicose veins	24	0	0	28	1	0
Arterial—lower limb	5	0	1	4	0	1
Amputations—lower limb	3	0	0	1	0	0
Total clean	49	0 (0%)	2 (4·1%)	53	2 (3·8%)	3 (5·7%)
Potentially contaminated						
Stomach	5	3	1	11	4	2
Gallbladder	7	0	0	17	8	2
Gridiron appendicectomy	11	0	0	14	3	0
Bladder	6	0	0	4	0	2
Kidney	1	0	0	1	0	0
Infected lesions	1	0	0	1	0	0
Colorectal and perforated appendicitis	6	1	1	5	2	1
Total potentially contaminated	37	4 (10·8%)	2 (5·4%)	53	17 (32·1%)	7 (13·2%)

The difference between the primary sepsis rates in potentially contaminated wounds is significant ($\chi^2 = 5{\cdot}5$, $P < 0{\cdot}02$).

Table II: ORGANISMS CULTURED FROM SEPTIC WOUNDS

	Primary sepsis		Secondary sepsis	
Organisms	Clean	Potentially contaminated	Clean	Potentially contaminated
Staphylococci	2	6	3	6
Intestinal organisms	0	10	1	3
Pus sterile or not sent	0	5	1	0

contaminated wounds the sepsis rate was higher with povidone-iodine than with cephaloridine (*Table I*), but the difference reached statistical significance only in the potentially contaminated group ($\chi^2 = 5{\cdot}5$, $P < 0{\cdot}02$), and the trial was therefore stopped for ethical reasons.

In the majority of cases (3 out of 4 with cephaloridine and 11 out of 19 with povidone-iodine) the wound sepsis was of minor importance—a stitch abscess or its equivalent. Twelve wounds discharged pus during the first 7 days after operation and 11 on the eighth day or later, the longest interval being 31 days.

In 66 of the 90 potentially contaminated cases in this series an operation swab was cultured, and an organism was found in 37. Eight were staphylococci, sensitive to cephaloridine, and 29 were intestinal organisms all but 3 of which were sensitive to cephaloridine. In the 29 cases in which the operation swab was sterile, wound sepsis developed in 6 (21 per cent). When an organism was cultured at operation, 12 out of the 37 wounds subsequently discharged pus (33 per cent). This difference lacks statistical significance ($\chi^2 = 1{\cdot}13$, $0{\cdot}30 > P > 0{\cdot}20$). Whether or not the operation swab was sterile, wounds were less likely to become septic when cephaloridine was used for prophylaxis than when povidone-iodine was the agent employed (3 out of 25 compared with 15 out of 41, $\chi^2 = 4{\cdot}73$, $P < 0{\cdot}05$).

When we came to correlate the bacteriology at operation with that of pus from the 23 primarily infected wounds, we found that in 15 cases one of the swabs was sterile or had not been taken. Of the remaining 8, the pus subsequently cultured from 5 of the wounds yielded an organism apparently identical with that found at operation, and in 3 the organism differed from the one previously cultured.

Secondary infections

In 4 of the 86 patients receiving cephaloridine (5·1 per cent) and 10 of the 106 patients receiving povidone-iodine spray (9·4 per cent) secondary wound sepsis developed (*Table I*). This difference is not significant ($\chi^2 = 1{\cdot}60$, $0{\cdot}30 > P > 0{\cdot}20$).

Of these 14 patients, the initial discharge in 5 was of peritoneal fluid associated with an intraperitoneal drain (3) or a burst abdomen (2). In 2 patients the first discharge was of serum from a haematoma and in 2 of lymph from the groin after operation on the femoral artery. Four patients developed secondary sepsis after other fistulas (2 urinary, 1 biliary and 1 salivary), and one arose as a result of ischaemic sloughing of a wound edge.

Five of these secondary infections arose in clean wounds, and 9 in potentially contaminated wounds. In only one was the organism cultured from the wound the same as that cultured at operation. There was, therefore, no correlation between the nature of bacterial contamination at operation and subsequent secondary wound infection.

Discussion

Most primary wound infections occur during surgery from endogenous sources (due to opening of potentially contaminated hollow muscular viscus or excision of an infected lesion). Provided that normal aseptic precautions are taken, contamination from exogenous sources such as the operating theatre air, surgeons' hands or unsterile instruments is exceedingly uncommon (Report, 1964; Davidson and Smith, 1969; Davidson et al., 1971). The rare primary infections after clean operations are usually explicable by contamination from the patient's nose or skin or by haematogenous seeding (Howe, 1968).

Secondary wound sepsis, on the other hand, does not arise as a result of infection of the wound during operation and cannot be prevented by applying antibacterial substances to the wound. This prophylaxis depends on the prevention of haematomas and fistulas and the avoidance of cross-infection in the ward. It is in this connection that the currently accepted ward architecture of small rooms, individually ventilated, is so important (Smith et al., 1974). It is almost impossible in a large multi-bedded ward to maintain the sterility of a discharging wound. *Table II* shows that the predominant organism in primary wound infections is intestinal, whereas staphylococci are commoner in secondary infections.

In the present trial cephaloridine proved to be much more efficient than povidone-iodine in the prevention of primary wound infections. Secondary infections also were commoner with povidone-iodine, and this may reflect an irritative property of this substance leading to effusion of serum which subsequently discharges and becomes infected.

Our very unsatisfactory results with povidone-iodine contrast with those reported by Gilmore and Martin (1974), whose trial was confined to gridiron appendicectomies. In their series, excluding cases of perforated appendicitis, 15 out of 136 (11·0 per cent) in the control group discharged pus compared with 6 out of 135 (4·4 per cent) in the povidone-iodine group ($\chi^2 = 4 \cdot 11$, $P < 0 \cdot 05$). One has to postulate only a single missed infection in the latter group to reduce χ^2 to 3·10 and remove the statistical significance.

In the present series no grid iron appendicectomy wounds out of 11 discharged pus in the cephaloridine group compared with 3 out of 14 which received povidone-iodine. This difference by itself cannot be significant and it is only when the sepsis rate of all potentially contaminated operations is considered that cephaloridine emerges as a significantly better prophylactic agent than povidone-iodine.

Despite the theoretical danger of the encouragement of resistant organisms by the local use of a potent systemic antibiotic for wound infection prophylaxis, the present trial demonstrates that this must continue to be our practice until an equally effective alternative is available.

Bacteria in flower vase water: incidence and significance in general ward practice

C. A. BARTZOKAS, MARGUERITE P. HOLLEY AND CHRISTINE A. SHARP*

SUMMARY

Culture of flower vase water from wards in the David Lewis Northern Hospital, Liverpool, revealed large numbers of potentially pathogenic bacteria. The types of organisms isolated may reflect the particular ecology of this hospital as they differed in some ways from those reported from other centres. The incidence of wound infections during the period of study was low (5·2 per cent) despite the regular overgrowth of bacteria in flower vases, and there did not appear to be any definite correlation between the types of bacteria isolated from flower vase water and those responsible for wound infections.

The addition of hydrogen peroxide to flower vases proved a very effective antiseptic and is recommended for general use as a precautionary measure.

There have been several conflicting reports on the potential hazard in hospital practice of bacteria growing in flower vase water. Thus, whereas Watson and Koons (1973) considered that *Pseudomonas aeruginosa* cultured from ornamental flowers may be responsible for some hospital infections, Schroth et al. (1973) indicated that definite proof of pathogenicity was lacking despite the fact that 50 per cent of the strains of *Pseudomonas* isolated from plants had similarities to human ones. Furthermore, Hughes (1974) considered that flowers in hospital wards were probably the victims rather than the source of human bacterial infections. On the other hand, Taplin and Mertz (1973) concluded that the growth of Gram-negative bacteria in flower vase water may be responsible for the transmission of hospital infections, and Ansorg et al. (1974) reported a case of septicaemia due to *Erwinia* spp. which led to the death of a debilitated patient.

The problem of bacterial overgrowth in flower vase water needs therefore to be reassessed, and several studies in different hospital environments are required before a true picture of its exact significance can be ascertained. For these reasons we decided to investigate the problem at the David Lewis Northern Hospital, where over a period of 6 months cultures were made of the flower vase water from wards and a record kept of the incidence and bacteriology of all postoperative wound infections during the same period of time.

Materials and methods

In this hospital the flowers usually given to patients consist of carnations, chrysanthemums, freesias, lilies of the valley, marguerites, roses and tulips. Cut flowers are put into vases containing 1 litre of tap water and changed at the sink in the sluice daily by the ward orderlies.

The bacterial flora of water from flower vases was initially studied. Samples were taken from 60 vases in 9 general wards at this hospital. Before sampling, the flowers were gently agitated and 5 ml of the flower water were transferred with a sterile Pasteur pipette to a sterile container. Within 1 hour of sampling the water was inoculated on to Oxoid MacConkey agar and blood agar plates, using a standard platinum wire loop. No addition of sodium thiosulphate (to eliminate chlorine residues) was made to the culture media, as Taplin and Mertz (1973) reported no significant difference in results with and without this substance. The plates were incubated for 24 hours at 37 °C and for a further 24 hours at room temperature (17–25 °C). In addition the tap water and swabs from the inside of the water taps in the wards were cultured in a similar way. The bacterial growth was then assessed by visual means as 'heavy', 'moderate' or 'light'. Colonies were subcultured whenever it was deemed necessary. Medical bacteria were identified by Gram reaction, morphology, spores, motility, catalase, oxidase, O–F tests, carbohydrate breakdown, ability to grow in air and secondary tests, as described by Cowan and Steel (1966).

In order to study the effect of hydrogen peroxide a further 7 vases from the same ward environment were sampled by the same method and cultured on to MacConkey agar. Further cultures were made 1, 2, 8, 24 and 48 hours after the addition of 50 ml of 10 volumes hydrogen peroxide to each vase. The flowers were left for 72 hours in the same water to see if the added hydrogen peroxide in any way affected the state of the flowers.

In another experiment powdered maganese dioxide was added to the culture media before plating the inocula of further flower vase water previously treated with hydrogen peroxide. Manganese dioxide was included as a neutralizer of H_2O_2 to ensure that the latter was not inhibiting bacterial growth in the culture medium.

The incidence and bacteriology of postoperative wound infections were analysed during the period of study. The wards in this hospital are of the open Nightingale type. Wound sepsis was accepted only when culture from the wound or its discharge was positive for pathogens. The operations were classified as 'clean', e.g. thyroidectomies, 'potentially infected', where there was a risk of contamination during

operation, e.g. operations on the gastro-intestinal tract distal to the upper jejunum, and 'infected', including operations carried out in the presence of established sepsis, e.g. drainage of abscesses and surgery for peritonitis, etc.

Results

Flower vase water with no additives

A heavy growth of mixed bacteria was obtained from all 60 samples studied from the 9 wards during a period of 6 months. There was an overall predominance of *Escherichia coli* and the Enterobacter/Klebsiella group of organisms. No *Proteus* or *Pseudomonas* spp. were isolated. The tap water and swabs from the taps showed a scanty growth of saprophytic bacteria only.

Effect of hydrogen peroxide

A moderate to heavy mixed growth of organisms was initially obtained from 7 vases which were subsequently treated with hydrogen peroxide. There was no growth in 35 samples taken from the same vases at intervals of 1–48 hours after treatment with hydrogen peroxide. The addition of hydrogen peroxide to the water produced no detrimental effect on the flowers.

Effect of manganese dioxide

A similar growth inhibition was obtained in hydrogen-peroxide-treated specimens even when manganese dioxide was added to the culture media.

Postoperative wound infections

During the course of the study there was a total of 46 postoperative wound infections (*Table I*) out of a total of 880 operations. The organisms isolated are shown in *Table II*.

Discussion

The present study shows an alarming incidence of bacterial growth in flower vases in this hospital. The most common organisms grown were *Escherichia coli* and those of the Enterobacter/Klebsiella group.

It is interesting that, contrary to previous reports, neither *Proteus* nor *Pseudomonas* spp. were cultured on any occasion during the course of this study. This may be a reflection of the bacterial ecology of this hospital. Despite the heavy growth of bacteria from flower vase water from surgical wards we encountered an overall incidence of postoperative wound infections of only 5·2 per cent. The three most common organisms cultured from postoperative wounds were *E. coli*, *Staphylococcus aureus* and *Proteus* spp. which respectively accounted for 1·13, 1·02 and 0·9 per cent of infections. We did not type the *E. coli* from the flower vase water or those isolated from wound infections and it is possible they were of the same strain. However, the general lack of correlation between the bacterial flora of flower vase water and that cultured from postoperative wounds, together with the low incidence of wound infections encountered during the period of study, argues against flower vase water being responsible for the production or transference of wound infections. Indeed in this hospital where flower vase bacteria were routinely grown during the period of study, the incidence of postoperative wound infection was well below the national average of 9·7 per cent reported by the Public Health Laboratory Service (1960). It must, of course, be stressed that the patients we studied had no evidence of depressed resistance to infections, and certainly none of the infections could be classed as opportunistic in nature. It is conceivable, and indeed likely, that flower bacteria may produce serious infections in severely debilitated patients and this has been reported (Ansorg et al., 1974). In any event the addition of hydrogen peroxide results in effective decontamination of flower vase water and we recommend the addition of this chemical as a precautionary measure.

Treatment of flower vase water with antiseptics has previously been reported (Smellie and Brinklow, 1963; Johansen et al., 1974). Our studies have confirmed the preliminary reports of Rosenzweig (1973) in that hydrogen peroxide was found to be very effective in preventing the growth of bacteria in flower vase water. The results obtained when manganese dioxide was added to the culture media indicates that growth inhibition was not due to any direct action of hydrogen peroxide in the culture media itself.

Analgesic abuse in urological practice

R. W. PARKER AND RICHARD E. SHAW*

SUMMARY

Thirty-three patients seen in a urological department had taken large doses of analgesic for prolonged periods of time. In 9 cases a diagnosis of pyramidal necrosis was established, while 4 others had pyelographic evidence of pyelonephritis, and analgesic abuse was probably an important aetiological factor in their renal condition. Analgesic nephropathy is easily overlooked unless patients are questioned routinely regarding their intake of analgesic. It is important to identify the group of patients without evidence of serious renal disease who are taking excessive quantities of analgesic and to urge them to abandon the practice.

PAPILLARY necrosis was first described in 1877 by Von Friedreich who observed the condition in association with obstructive uropathy caused by prostatic hypertrophy. As further cases were reported links with acute pyelonephritis, diabetes mellitus and obstruction in the urinary tract were established. In Switzerland Spühler and Zollinger (1953) described an autopsy series of 30 patients afflicted with a condition which they termed 'interstitial nephritis', and which was associated with consumption of phenacetin-containing analgesics. In 22 out of 30 cases there was papillary necrosis, but there was no incidence of diabetes or of urinary obstruction. Since then a substantial number of papers have appeared dealing with 'analgesic nephropathy', as the condition has come to be known, although by 1970 only 44 cases had been reported in England and Wales (Koutsaimanis and de Wardener, 1970).

Patients

During the years prior to 1973, 9 cases of analgesic nephropathy received treatment in the Urological Department at Walsgrave Hospital, Coventry, and the details of these cases are analysed below. In addition, 24 patients were seen who had taken excessive amounts of analgesics for prolonged periods of time, and this group will receive examination later in the paper.

Analgesic nephropathy (*Table I*)

Sex and age

Of the 9 cases, 8 were female, giving a female to male ratio of 8 : 1. This is in harmony with general experience of this disorder. The age at the time of presentation varied from 24 to 66 years, with an average of 53 years. De Wardener (1973) stated that the diagnosis is usually made around the age of 50.

Presenting symptoms

The 9 patients presented with symptoms of a varied nature. Two were admitted in renal failure, 7 had symptoms of infection such as dysuria, frequency and haematuria and 1 was admitted with septicaemia. Four complained of renal pain or had actual ureteric colic, and 1 of these patients passed necrotic papillae in the urine. The length of the clinical history varied from 1 month to 9 years with an average of 22 months, but of course the history of analgesic intake was much longer, being from 8 to 30 years with a mean of 14 years.

Amount of analgesic consumed

An attempt was made to estimate the total amount of analgesic taken—not an easy task because of the vagueness of the history, and in some cases an element of deliberate concealment. The results are shown in *Table I* and indicate a wide variation. At one extreme only 0·6 kg of phenacetin was taken, while at the other, consumption was 39 kg each of aspirin and phenacetin (*Case* 7) which corresponds to 100–150 tablets of codeine per week for 20 years. Fortunately, intake of this order does not necessarily lead to renal damage. We have records of a patient with ankylosing spondylitis who took 6–9 Phensic tablets daily for 28 years; at the end of this time his intravenous pyelogram was normal and the creatinine clearance 110 ml/min. His wife included a bottle of tablets in her weekly shopping list. De Wardener (1973) said the amount of phenacetin needed to produce radiological changes varied from 1 to 25 kg taken for a period of from 2 to more than 20 years.

Clinical features

Urinary infection

Infection of the urinary tract was present in all our cases, the responsible organism being coliforms in 5 instances, *Proteus* sp. in 3 and *Streptococcus viridans* in 1. The infection often proved resistant to treatment. The incidence of infection has varied widely in different reports. Patients may present with sterile pyuria; in fact some authors have found analgesic nephropathy to be a more frequent cause than tuberculosis of this urinary abnormality.

Anaemia

All the patients had reduced haemoglobin levels. In 5 cases the anaemia was severe, with values between 6·0 and 7·5 g per cent. As might be expected, this group included those with the heaviest intake of analgesic. A high incidence of anaemia has been noted in other reported series of cases. The anaemia is iron-deficient in type and important factors in its genesis include the effect of aspirin on

* (Age, sex).

the gastrointestinal tract and poor renal function. In several of our cases the erythrocyte sedimentation rate was elevated.

Hypertension

In 5 patients the diastolic pressure was over 90 mm Hg and 2 of the patients had moderately severe hypertension. In 1 patient the blood pressure rose rapidly from 150/90 to 230/140 in the course of 3 months following the diagnosis of the condition. Another became hypertensive about 2 years after analgesic nephropathy had been diagnosed and the intake of analgesic had been abandoned. The reported incidence of hypertension varies from 33 to 75 per cent.

Renal function

Two patients were suffering from frank renal failure when first seen, but in 5 others reduced renal function was shown by a raised blood urea, reduced creatinine clearance or both. The incidence of severe renal impairment varies a good deal in different series and is probably related to variations in the sources of material. The earliest defects in renal function are loss of the ability to concentrate urine due to destruction of medullary tissue, and inability to excrete an acid load.

Psychological disturbance

Four of our 9 patients had evidence of mental abnormality. One suffered from chronic alcoholism, another was a regular attender at hospital with unexplained symptoms and 2 volunteered that they suffered considerably from nervous trouble. With increasing experience of the disorder, we came to recognize a rather withdrawn type of personality associated with the syndrome. Gault et al. (1968) found that one-third of his patients had had psychiatric treatment, mainly for anxiety, marital disharmony, depression drug-taking other than analgesics and alcoholism. Murray et al. (1970) commented that analgesic nephropathy was uncommon among psychotics, but associated with neurosis.

Peptic ulceration

One patient had undergone partial gastrectomy for benign gastric ulcer which had presented 3 years after the abuse had started but 12 years before the onset of renal symptoms, while another had a long history of dyspepsia and had suffered several haematemeses, although no ulcer was demonstrated by barium studies. Dawborn et al. (1966) have discussed the association of peptic ulceration, chronic renal disease and analgesic abuse, and found peptic ulceration present in 30 out of 92 cases of papillary necrosis due to excessive intake of analgesics. Peptic ulceration, or the aggravation of pre-existing ulceration, may be attributed to the aspirin rather than the phenacetin intake, and is not found in the patients who have not taken aspirin as part of the analgesic intake (Gault et al., 1968).

Radiological diagnosis

Confirmation of the diagnosis of analgesic nephropathy depends upon pyelographic evidence of renal change. In our early cases poor renal function frequently prevented us from obtaining good intravenous pyelograms, and retrograde pyelography or ascending ureterography was needed. More recently, the use of high dose urography has facilitated the detection of renal abnormalities, but we still find the ascending ureteropyelogram affords the best pictures. The early signs of disease are poor concentration of dye in the calices, widening of the caliceal fornices due to papillary shrinkage, irregularity of papillary outline and offshoots of the dye into the papillae, indicating their early separation. Later signs are the presence of medullary cavities of various sizes (*Fig.* 1), ring shadows caused by sloughs lying in dye-filled cavities (*Fig.* 2),

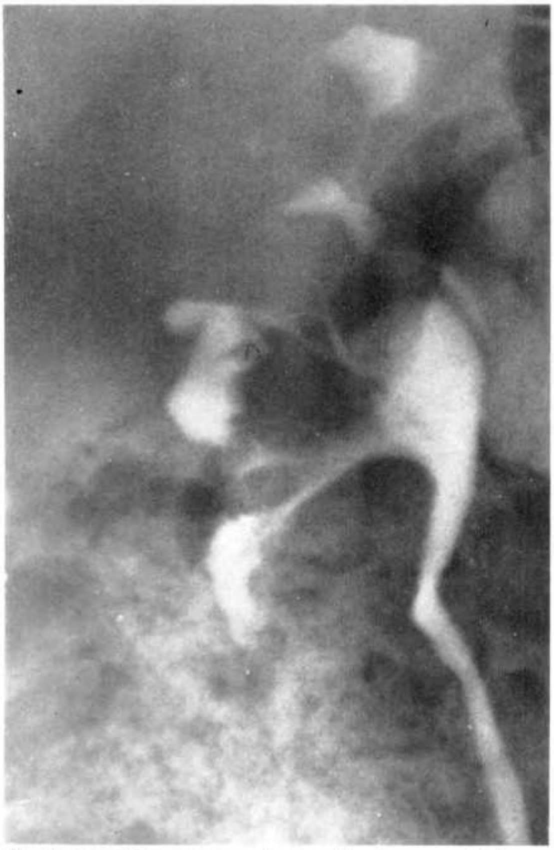

Fig. 1. Ascending ureteropyelogram showing pyramidal necrosis. Multiple cavities of irregular outline are visualized.

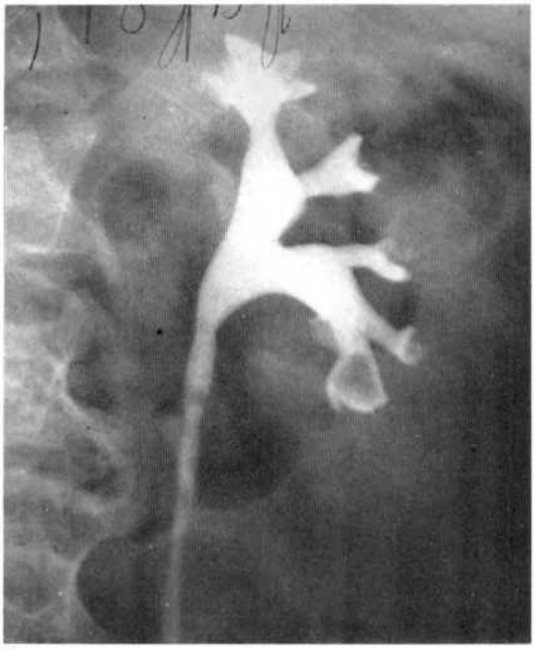

Fig. 2. Ascending ureteropyelogram showing pyramidal necrosis. A pyramid in the lowest calix has separated completely.

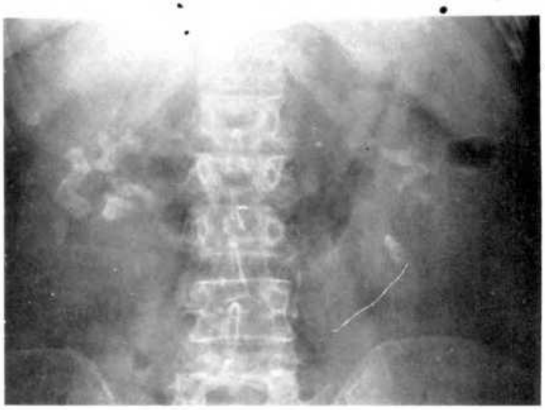

Fig. 3. Renal calculi secondary to pyramidal necrosis showing characteristic translucent centres.

calcification of papillae and finally shrinkage of the kidneys. The necks of the calices often appear elongated (*Fig.* 1). Lindvall (1960) found that papillary calcification only occurred in the presence of sloughing of the papillae and urinary infection with *Proteus* sp., and that 'without these factors stone formation was very rare'. Further deposits of calcium lead to the formation of calculi with radiotranslucent centres, producing a characteristic appearance (*Fig.* 3). Surgeons should be on the look-out for this type of stone and seek a history of analgesic abuse from the patient. In 6 of our 9 cases medullary cavities were shown. In one case papillary calcification was observed and another patient had multiple calculi with translucent centres. A reduction of the overall size of the kidneys or localized cortical thinning was noted in 3 cases. Two showed filling defects caused by sloughing of pyramidal tissue.

Reason for excessive analgesic intake

Two patients had legitimate reasons for taking analgesics, namely suffering from arthritis. The remainder took tablets for 'migraine' (although none suffered from true migraine), headaches or indefinite generalized pains. Several patients were vague about their reasons and were reluctant to volunteer information; they seemed unable to appreciate the irrationality of taking a drug day after day for intermittent symptoms such as headache. One was left with the impression that they obtained a sense of uplift and well-being from taking the tablets. A knowledge of medical matters did not preclude addiction, since one of the 9 cases was a qualified midwife and another was a nurse and the wife of a medical practitioner. Prescott (1966) found headache the commonest reason for addiction and arthritis the second most frequent. Dawborn et al. (1966) gave first place to headache, with psychological upset as the next most frequent cause, while factory workers reported by Nordenfelt and Ringertz (1961) took powders to increase their concentration at work.

Concealment

Patients indulging in analgesic abuse are usually very unwilling to admit to their addiction. One must be prepared to sit down with the patient and gently, but remorselessly drag out the details. Whether from shame or suppression of the facts into the unconscious, they have immense difficulty in providing information regarding the duration of intake, frequency of self-administration and the daily or weekly dose. In time, one usually establishes a satisfactory picture, but even so, the assessments of the total intake of tablets by our patients were almost certainly underestimates.

Diagnosis

A typical case of analgesic nephropathy is a middle-aged woman with psychological problems complaining of symptoms of persistent and often severe urinary infection with signs of impaired renal function and anaemia. Dyspeptic symptoms may also be present. The initial diagnosis is often chronic pyelonephritis, but a history of excessive analgesic intake alerts the surgeon who may then find in the pyelographic studies evidence of destruction of medullary tissue as shown by one or more of the signs described above. As de Wardener (1973) puts it, 'the diagnosis is made by asking the right questions'. Unlike chronic pyelonephritis, the disease is always bilateral. The type of case most easily diagnosed is the patient who passes in the urine one or more sloughing pyramids which can then be indentified histologically. The type of pyramidal necrosis associated with diabetes runs a more acute course and is less common than analgesic nephropathy—we have seen only 2 cases during the same period.

Treatment

The treatment of analgesic nephropathy involves: (1) withdrawal of phenacetin, (2) treatment of urinary tract infection, (3) treatment of renal failure, if present, and (4) in some cases, surgical removal of obstructing pyramidal tissue.

The most important element in treatment is to stop the intake of phenacetin. One patient, who suffered from severe arthritis, refused steadfastly to abandon her codeine tablets without which she claimed life was intolerable. Although her son was a chemist, she would not accept any alternative analgesic, and her condition declined until she was lost to follow-up on leaving the district. Two other patients died within 2 months of the condition being diagnosed. Surprisingly, the remaining patients appeared to have no difficulty in abandoning a habit of many years' duration, and in each case renal function then slowly improved or in one case remained unchanged, while their general health also progressed favourably. Bell et al. (1969) showed that after withdrawal of the analgesic, renal function usually improves or remains stable, and only occasionally shows a slow decline. Our experience matches this. Urinary infection requires treatment by long term antibiotics. One of our patients (*Case* 2) showed steady improvement in her general condition and renal function following the withdrawal of the analgesic, the blood urea steadily falling to normal, but she became hypertensive and, in spite of prolonged therapy, urinary infection was never eradicated.

Surgical treatment

Separated papillae, especially if calcified, may cause blockage of the ureters and exacerbation of infection in pyramidal necrosis, whether caused by analgesic abuse or by diabetes. Hendry et al. (1972) described how these fragments, together with pus and debris, may be removed by a pyelotomy, and at the same time fragments lying in the ureter can be milked up or withdrawn using a Fogarty catheter. Fragments obstructing the lower ureter may be extracted with a stone basket (Hellebusch, 1969). We have not had occasion to employ these surgical measures, which are particularly indicated in the more acute type of pyramidal necrosis found in diabetes. In operating on cases of analgesic nephropathy, the experience of Koutsaimanis and de Wardener (1970) should be borne in mind. They reported that operations on patients with analgesic nephropathy carried a high mortality due to rapid deterioration of renal function. These patients are very susceptible to fluid loss, and preoperative dehydration, aggravated by hypotension and sodium loss, may reduce the medullary blood flow and compromise the vitality of the remaining papillae. Special attention must be paid to maintaining adequate hydration if operative treatment has to be carried out.

Analgesic abuse in other urological patients

In addition to the 9 patients discussed above, 24 patients were seen in the Urological Department who admitted taking excessive quantities of analgesics. We have arbitrarily defined analgesic abuse as an average dose of 10 tablets of codeine (or equivalent) per week, taken regularly for a minimum period of 2 years, but have relaxed this criterion to include 2 patients taking rather smaller doses for a much longer period of time and 1 patient who imbibed an enormous dose (140 codeine tablets weekly) for 9 months only. These patients had a similar sex and age distribution to those who were found to have fully developed analgesic nephropathy. Twenty of the 24 (83 per cent) were female and their ages varied from 20 to 67 with an average age of 41 years. Excessive analgesics were taken for periods varying from 9 months to 28 years with a mean of 8 years. In 6 cases the drugs were taken for the relief of arthritis or rheumatic conditions, but the remainder gave as their reasons either headache or 'migraine'. The analgesics favoured by the patients were mixtures containing phenacetin but, exceptionally, 2 patients took aspirin only. In 19 instances the intravenous pyelograms were normal. One patient had a stone in the right renal pelvis without evidence of pyramidal destruction. In 4 patients there was evidence of chronic pyelonephritis shown by clubbing of the calices and shrinkage of renal tissue. This group of 4 cases is important, as it may well include examples of analgesic nephropathy. The possibility of pre-existing pyelonephritis cannot be excluded, but analgesic abuse as a prime cause of the renal changes is suggested by the fact that 3 out of the 4 had abandoned analgesics a few years before they were seen by us. The pyelographic appearances may therefore represent a healing phase in the disorder. Reduced creatinine clearances indicated depressed renal function in 3 of the patients, 1 of whom was hypertensive. Of the 19 patients with normal intravenous pyelograms, 4 were hypertensive and 2 others had reduced creatinine clearances, but it is not possible to relate these findings firmly to their abuse of analgesics. None the less, in all these cases the renal tract is at risk, and all were urged to abandon the habit.

Discussion

Analgesic nephropathy is easily overlooked. Koutsaimanis and de Wardener (1970) estimated that there could be 500 new cases in England and Wales per annum, but by 1970 only 44 cases had been reported in the literature. It is imperative that all patients attending hospital with urinary symptoms should be questioned about analgesic intake. Any ambiguity in the reply should lead to closer interrogation, and the frequent concealment of the habit and underestimation of the dose should be remembered. The possibility of analgesic abuse should be borne in mind in cases of renal failure of unknown origin, in progressive chronic pyelonephritis and in patients with renal calculi or presenting with renal colic. Sterile pyuria may be a useful lead, and discovery of renal calculi with radiotranslucent centres should at once arouse the surgeon's suspicion. As mentioned above, we have records of 24 patients with excessive intake of analgesic associated with urinary symptoms but in whom we were unable to obtain radiological evidence of destruction of renal tissue. It is important that this group of patients should be identified, as the disease may be prevented by inducing the patients to abandon their addiction. In this way, not only may renal involvement be averted, but the patient may be spared the risk of developing carcinoma of the renal pelvis (Angervall et al., 1969). There is reason to believe, however, that analgesic nephropathy is a disease which will soon decline in frequency. Not only is the medical profession now familiar with the disorder, but presentations on television and other media have alerted the general public to the dangers of analgesic abuse. Some manufacturers have withdrawn phenacetin from their analgesic mixtures. The Department of Health and Social Security has restricted the sale of phenacetin-containing compounds to pharmacies only from 1 June 1974, and from 1 January 1975 phenacetin has been available only on a doctor's or dentist's prescription.

Although the finger of suspicion points most clearly to phenacetin as the responsible drug, it is still uncertain whether it is the only analgesic capable of inducing pyramidal necrosis, despite much clinical and animal research. We will not enter into details of this difficult problem, but until the matter is elucidated the clinician would be wise to regard both phenacetin and aspirin as culpable. Paracetamol, once regarded as innocent, has been implicated as a cause of analgesic nephropathy (Krikler, 1967), which is not surprising since paracetamol is a metabolic derivative of phenacetin. We have studied one case, not included in this series, in which pyramidal necrosis followed ingestion of paracetamol alone.

The Fowler–Weir approach to appendicectomy

A. R. ASKEW*

SUMMARY

The medial approach of Fowler–Weir enables rapid opening of the abdominal cavity and provides good access to the appendix. Although there is less muscle trauma the wound seems as painful postoperatively as with the classic muscle-splitting approach. However, morbidity is less as shown by a decrease in the wound and deep infection rate compared with that after appendicectomy by the McBurney approach.

APPENDICECTOMY is the commonest abdominal surgical emergency, and since McBurney's classic description of appendicectomy in 1894 there have been numerous accounts of modifications, especially of the skin incision. Apart from the now obsolete Battle approach, the major modification to the approach to appendicectomy was published independently by George Fowler and Robert Weir in 1900. The Fowler–Weir approach has been evaluated in a series of 54 cases and compared with the classic muscle-splitting approach performed in a further 56 cases.

Materials and methods

One hundred and ten consecutive patients undergoing appendicectomy over a 10-month period were evaluated. Fifty-four patients were operated on by the Fowler–Weir (medial) approach and 56 by the standard right iliac fossa muscle-splitting approach. *Table I* summarizes the patients.

The indications for drainage of the wound and peritoneal cavity were standardized, as was the wound closure. An antibiotic spray (Framyspray) was sprayed into the wound in all cases. Postoperatively the number of analgesic injections required in each case was noted. The development of wound infection or deep abscesses was recorded.

In the Fowler–Weir approach the abdomen is opened by a skin incision overlying the lateral border of the right rectus abdominis muscle at or below the level of the anterior superior illiac spine (*Fig.* 1). The external oblique aponeurosis is then incised in the line of its fibres and the incision is extended horizontally across the anterior rectus sheath (*Fig.* 2). Medial retraction of the rectus muscle and the inferior epigastric vessels allows good exposure of the transversalis fascia and peritoneum which is then easily picked up and incised (*Fig.* 3). Closure of the wound is in layers with catgut, silk sutures being used for the skin.

Results

a. Non-perforated group

Forty-six patients in the Fowler–Weir group had non-perforated organs removed compared with 47 patients in the muscle-splitting group. Ten non-inflamed appendices were removed (9 per cent overall); 4 in the first group and 6 in the second.

In the Fowler–Weir group there were 4 cases of wound infection and 5 cases in the McBurney group. One patient in the former group developed a pelvic abscess.

Postoperative pain is difficult to assess but in the second to fourth decades when the condition is most common there was no great difference in the requirements of intramuscular analgesics of patients with non-perforated organs (*Table II*).

Table I: DETAILS OF THE PRESENT SERIES

	Fowler–Weir approach	McBurney approach
Total no.	54	56
Male	25	31
Female	29	25
Non-perforated	46	47
Perforated	8	9
Overall infection		
Wound	6 (11%)	9 (14%)
Deep	2 (3·7%)	3 (5·4%)

Table II: ANALGESIA REQUIREMENTS IN THE NON-PERFORATED GROUP

	Fowler–Weir approach		McBurney approach	
Age (yr)	No. of patients	Average no. of injections	No. of patients	Average no. of injections
10–19	21	1·7	17	1·8
20–29	10	2·6	17	2·6
30–39	5	2·4	4	2·9

b. Perforated group

Seventeen patients with perforated organs were seen, 8 having appendicectomy by the Fowler–Weir approach. Of these, 2 patients developed a wound abscess and 1 a pelvic abscess. Of the 9 patients having a routine appendicectomy, 3 developed pelvic collections and 4 developed wound infections. Again there was no obvious difference in the analgesia requirements of the two groups.

Overall there were 6 cases of wound infection in the Fowler–Weir group (11 per cent) and 8 in the McBurney group (14 per cent). The incidence of deep infection was 3·7 per cent in the former group and 5·4 per cent in the latter.

Discussion

The McBurney approach to appendicectomy is probably the commonest method in use today. His original description in 1894 describes the muscle-splitting

Fig. 3. Retraction of the rectus muscle and inferior epigastric vessels to expose the transversalis fascia which is incised.

technique following incision of the external oblique aponeurosis. The skin incision is made at right angles to a line joining the anterior superior iliac spine to the umbilicus, its upper one-third lying above the now famous McBurney's point. It is perhaps the skin incision which has undergone the most modification, and the skin crease incision of Lanz (1908) is now generally used.

In 1900 Fowler described his method of appendicectomy, but utilized an inverted L-shaped incision. He recommended his method for use in early cases and for 'interval' appendicectomy. Weir (1900) used the same approach for cases of acute appendicitis but did not describe the skin incision used.

The medial approach gives rapid access to the abdominal cavity and the access obtained is at least as good as that obtained by the classic approach. On 3 occasions further access was easily obtained by separation of the fibres of the internal oblique muscle in the lateral part of the wound, and this presents no greater difficulty than if extension is required with a classic approach. The approach presents little difficulty in obese patients, and the ovary is readily accessible providing there is good muscle relaxation.

The rapidity with which the abdomen can be opened and the minimal amount of muscle trauma are definite advantages in patients who are poor anaesthetic risks or who are on anticoagulant therapy. Jelenko and Davis (1973) recommended this approach for the latter group of patients. There is less muscle trauma with the medial approach, but this is not reflected postoperatively as assessed by the intramuscular analgesia requirements.

A theoretical objection is the opening of another tissue plane in an operation which has a high incidence of postoperative wound infection, but this has not been a problem in practice.

Although, surprisingly, the medial approach seemed no less painful in the postoperative period, the minimal muscle derangement may be an important factor in the subsequent development of wound infection. This is especially important in the perforated case, and in this group the incidence of wound infection was halved using the Fowler–Weir approach.

NEW
Praxilene
vasoactivator
INJECTABLE
RELIEVES REST PAIN

for peripheral vascular disorders

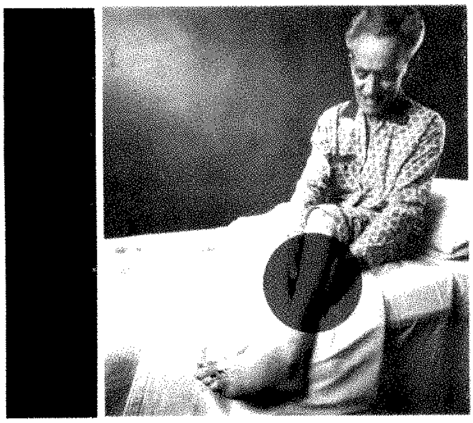
NEW Praxilene

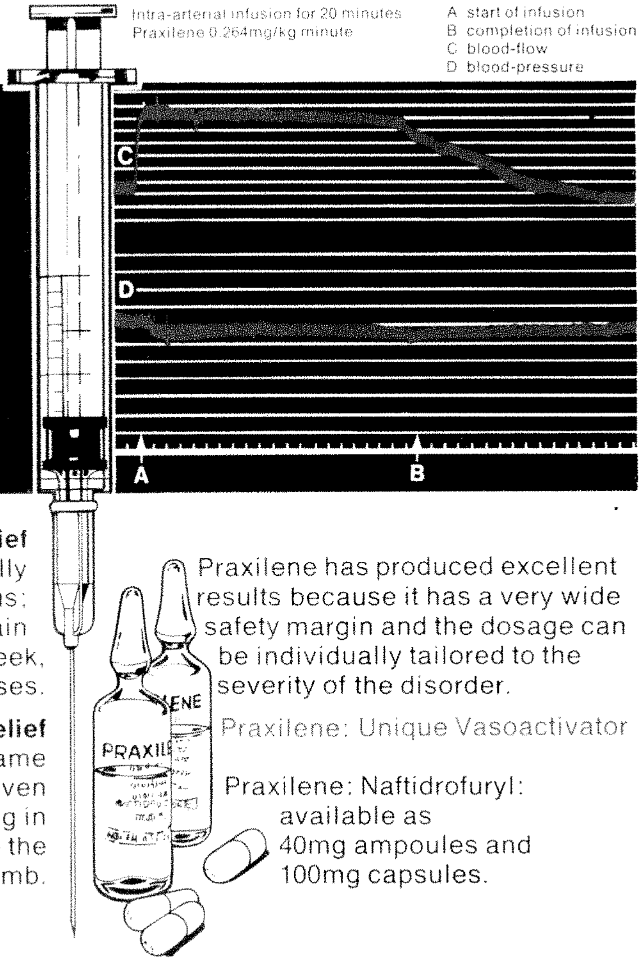
vasoactivator

INJECTABLE

RELIEVES REST PAIN

by flushing out pain producing metabolites
by improving blood-flow – without affecting blood-pressure
by a unique metabolic activity





Fast relief
Praxilene administered parenterally (Intra-arterial; Intravenous; Intramuscular) can give relief of pain within as short a time as one week, in many cases.

Prolonged relief
Relief of pain is prolonged: at the same time the collateral circulation is given the opportunity to develop, resulting in an improved blood supply to the affected limb.

Praxilene has produced excellent results because it has a very wide safety margin and the dosage can be individually tailored to the severity of the disorder.

Praxilene: Unique Vasoactivator

Praxilene: Naftidrofuryl:
available as
40mg ampoules and
100mg capsules.

Subphrenic abscess in children

M. MACKENZIE, J. FORDYCE AND D. G. YOUNG*

SUMMARY

Nineteen consecutive cases of subphrenic abscess which were treated in the Royal Hospital for Sick Children, Glasgow, from 1962 to 1972 are analysed. This complication of intra-abdominal suppuration of surgery still carries a grave prognosis. Four of the patients died (21 per cent); 2 deaths were related to the subphrenic abscess while the remaining 2 were not directly related to the abscess. The mean hospital stay of the survivors was 59 days (range 30–122 days). The changing patterns of aetiology and presentation which have recently been emphasized in general surgical practice are not reflected in this paediatric series.

SUBPHRENIC abscess is a serious complication of intra-abdominal sepsis or surgery. Before the era of surgery and antibiotics this disease was usually fatal, with a mortality reported as 47·4 per cent (Barnard, 1908) and 50 per cent (Piquand, 1909). Despite surgical technical advances, Oschner and DeBakey (1938) reported a mortality of 32·8 per cent in operated cases and 89·9 per cent in non-operated cases. Since the introduction of antibiotic therapy the mortality rate has been reported as low as 7·5 per cent (Ozeran, 1967), but in most series it remains higher between 14 and 35 per cent with surgery, and 30–94 per cent without surgery (Wetterfors, 1959; Dineen and McSherry, 1962; Carter and Brewer, 1964; Magilligan, 1968; Sherman and Davis, 1969; Halasz, 1970; Konvolinka and Olearczyk, 1972).

Contemporary adult surgical experience shows subphrenic abscess to be a postoperative complication of surgery for a non-inflammatory condition or for a perforated peptic ulcer (Sanders, 1970a; Surakiatchanukul and Ram, 1973). In paediatric surgical practice the commonest cause is still the intra-abdominal infection of appendicitis or primary peritonitis where early surgery does not always avert a subphrenic collection. The clinical pattern in children is usually that of an acute secondary illness occurring soon after surgery for primary inflammatory disease. With widespread use of antibiotics the presentation is often insiduous (Moller, 1967; Sanders, 1970a), and this may cause delay in instituting specific therapy.

This review is of recent experience with subphrenic abscess in the paediatric age group. It has been made to determine the present aetiology, morbidity and mortality of this condition.

Patients

This study was based on 19 consecutive cases of proved subphrenic abscess treated at the Royal Hospital for Sick Children, Glasgow, in the 11 years from 1962 to 1972. Four patients had bilateral subphrenic abscesses, i.e. the total number of abscesses was 23. The mean age of the patients was 5 years 7 months, the youngest being an infant of 8 months and the oldest a 12-year-old girl. Ten of the patients were male. The length of time spent in hospital varied from 30 to 122 days.

During this 11-year period there was an average of 210 patients (range 160–253) admitted each year with clinical and histologically confirmed acute appendicitis. Subphrenic abscess occurred in 8 of these patients, i.e. an incidence of 0·35 per cent. In addition, a further 3 children were admitted with an established appendix abscess, but appendicectomy was only performed later as an 'interval' procedure. If patients with appendicitis and its complications are considered separately, then the incidence of subphrenic abscess is 0·45 per cent.

Table I: CLINICAL PRESENTATION AND SIGNS IN 19 PATIENTS WITH SUBPHRENIC ABSCESS

Sign or symptom	No. of cases
Pyrexia, temperature elevation >37·5 °C	17
Leucocytosis (>10 000/mm^3)	15
Abdominal pain	15
Abdominal swelling and tenderness	12
Haemoglobin < 10 g/100 ml	11
Basal atelectasis	11
Elevation of hemidiaphragm	11
Pleural effusion	6
Gas under diaphragm	6

Presentation

The common signs and symptoms of the 19 patients are presented in *Table I*. Pyrexia above 37·5 °C which had either failed to settle or having settled began to fluctuate was present in 17 patients. Temperatures ranged up to 39·5 °C. The general condition of the children varied from a child with general malaise to that of the severely ill and toxic patient. Abdominal pain was present in 15 patients, and in 12 there was abdominal distension and marked abdominal tenderness. Shoulder tip pain was not a prominent feature. In the younger patients this may have been attributed to poor localization of pain, but it was also uncommon in the older children. An increased respiratory rate and an unproductive cough were common symptoms. Leucocytosis with predominantly a polymorphonuclear increase ranging from 10 000 to 23 000/mm^3 was present in 15 patients.

The diagnosis was usually made on clincial grounds with supporting evidence from radiological investigation. Gas under the diaphragm was present in only 6 patients. Basal atelectasis, elevation of the diaphragm and pleural effusion were the commonest radiological signs and were present in 11 patients. When screening was performed limitation of movement of the hemidiaphragm on the side of the abscess was observed in every patient. Complete immobility of the diaphragm is probably a late manifestation of the condition since movement was retained with a subhepatic abscess better than with a suprahepatic abscess.

* Royal Hospital for Sick Children, Yorkhill, Glasgow.

Aetiology

The primary condition preceding subphrenic abscess is shown in *Table II.* Acute appendicitis was the primary disease in 11 patients, with primary Gram-positive peritonitis causing 4 of the remaining subphrenic abscesses. The 2 patients with abscesses resulting from elective surgery followed splenectomy for portal hypertension and an interval appendicectomy. The pelvic abscess was of unknown aetiology, no visceral abnormality being found at laparotomy. The patient with ulcerative colitis was a 9-year-old girl who had a 3-week history of the disease. She had emergency colectomy following perforation of the colon. A left subphrenic abscess was drained 2 days later.

Appendicitis

Eight of the patients with acute appendicitis were operated on within 12 hours of admission and each was noted to have a macroscopic perforation of the appendix. The peritoneal cavity was drained in all of these patients but they proceeded to develop a subphrenic abscess. One patient admitted 6 days after the onset of symptoms had a pelvic abscess drained initially but it was felt that the appendix could not be safely removed at that time. The other 2 patients had an apparently localized right iliac fossa mass on admission and were treated conservatively. Subsequently each developed signs of a subphrenic abscess which necessitated surgical intervention. Following discharge these 3 patients returned for interval appendicectomy, and in 1, closure of a faecal fistula from the caecum.

Table II: PRIMARY CONDITION PRECEDING DEVELOPMENT OF SUBPHRENIC ABSCESS

Primary condition	No. of cases	%
Acute appendicitis	11	57·9
Primary peritonitis	4	21·0
Postsurgical	2	10·5
Ulcerative colitis	1	5·3
Pelvic abscess	1	5·3

Primary peritonitis

The causative organisms of the Gram-positive peritonitis which was complicated by subphrenic abscess were *Staphylococcus aureus* in 3 patients and pneumococcus in 1. Two of these patients had early laparotomy as a definitive diagnosis had not been made. One patient, an 8-month-old infant suffering from staphylococcal peritonitis, was known to have chronic granulomatous disease, and one girl was subsequently extensively investigated for evidence of granulomatous disease but with negative results. Three of these patients had been generally well prior to and since their intraperitoneal infection. Two gave a history of recent throat infection and one had just recovered from measles when the abdominal signs developed.

Bacteriology

Table III presents the bacteria cultured from the pus in the subphrenic space. In 2 patients no organisms were cultured from the subphrenic pus. Each of these patients had been treated with ampicillin and ceporin and these drugs may have eliminated the causal organisms. Gram-negative organisms predominated, and with the exception of the primary peritonitis patients all the organisms cultured were in this group.

NG, No growth.

Treatment

The initial therapy was usually for the primary inflammatory process, and in 16 patients the initial surgery was combined with antibiotic therapy. Ampicillin and cerporin were the most commonly used antibiotics. The subphrenic abscess was diagnosed from 2 to 39 days after operation and was subsequently drained. Two patients with an appendix abscess were treated conservatively at first and a subphrenic abscess was suspected soon after admission. The subphrenic abscess was drained later when it was not resolving adequately on conservative therapy.

The site of the abscess has been classified in *Table IV*. In 4 children bilateral abscesses were present and these were suprahepatic. Subphrenic abscesses are primarily intraperitoneal, and in 14 patients drainage of the abscess was by direct approach without crossing uncontaminated peritoneal cavity. In the 4 bilateral cases an epigastric transperitoneal approach was made to the abscesses.

The drainage route is shown in *Table IV*. Six patients developed a pleural effusion but only 1 patient developed a purulent collection in the pleural cavity, and at autopsy on this child micro-abscesses were present in the lung. There were no other intrathoracic complications such as rupture of the diaphragm or bronchial fistula. In 3 patients drainage was inadequate and a second operation was necessary to drain the abscess. In addition to the administration of antibiotics, adequate fluid, electrolyte and blood, when necessary, therapy was supplemented by intravenous feeding. High calorie intake may be necessary for some time, e.g. a calorie intake of 140 Cal/kg body weight for 2–3 months in one child. This child had a klebsiella septicaemia and subsequently a candida septicaemia, at which time all antibiotic therapy was discontinued and antifungal therapy given. With continuing intravenous nutrition he slowly responded. When septicaemic this patient also required mechanical ventilation for 6 days until adequate spontaneous ventilation could be maintained again.

Mortality

Four patients died in this series. One of these was the infant with chronic granulomatous disease in whom the subphrenic abscess was a further complication of his primary disease. The child with ulcerative colitis also died on the morning following operation for drainage of the abscess. One patient of 21 months had acute necrotizing appendicitis in a subhepatic appendix associated with incomplete rotation of the gut. He died 32 days later with evidence of intraperitoneal, intrahepatic and pulmonary infection continuing. The remaining child with appendicitis died 17 days after admission and 9 hours after drainage of 600 ml of pus from a right subphrenic abscess.

Discussion

Subphrenic abscess in children has not shown the change in aetiology which has been reported in adults (Moller, 1967; Rosenberg, 1968; Sanders, 1970a). The present series corresponds more to the aetiology of subphrenic abscess in general surgery reported prior to 1940 (Barnard, 1908; Fifield and Love, 1926; Oschner, 1931; Oschner and DeBakey, 1938). The reasons for this are not altogether clear. Appendicitis continues to be the main predisposing factor, and delay in diagnosis of acute appendicitis still continues in children.

Table IV: SITE OF ABSCESS AND DRAINAGE APPROACH

Position	No. of cases	Drainage approach
Right suprahepatic	12	Anterior subcostal
Right infrahepatic	1	Posterior
Left suprahepatic	2	Anterior subcostal
Left infrahepatic	0	—
Bilateral	4	Epigastric

Subphrenic abscess was reported by Delario (1934) to be a complication in 0·9 per cent of patients with acute appendicitis, while earlier in this century Newhof (1912) reported the incidence as 1·5 per cent. More recently, Moller (1967) and Sanders (1970b) have reported the incidence of subphrenic abscess complicating appendicitis as 0·3 and 0·4 per cent respectively. This is in parallel with the Glasgow experience of 0·35 per cent when only histologically confirmed acute appendicitis is considered, and 0·45 per cent when in addition patients with clinically diagnosed appendix abscess are included.

In this series primary peritonitis preceded subphrenic abscess in 21 per cent of the patients. Primary peritonitis has been reported as a complication of Gram-positive bacteriaemia in children (Harken and Shockat, 1973). In the present series there were 3 staphylococcal abscesses and in only one of these children was a predisposing cause found. The suspected increase in primary peritonitis in patients with the nephrotic syndrome or those on steroid or immunosuppressive therapy has not yet resulted in intraperitoneal infection and subsequent subphrenic abscess.

The mortality in the present series remains high at 21 per cent. One infant died primarily from his chronic granulomatous disease. Repetition of the remaining 3 deaths may now be avoidable with the current armamentarium of antibiotics, intravenous fluids and feeding, assisted ventilation and intensive monitoring.

Direct treatment of the abscess remains along the basic lines of standard surgical practice. Once diagnosed a brief period of intensive antibiotics and resuscitative treatment may be beneficial to produce optimal conditions for drainage. The antibiotic to be used in each patient will depend on the primary condition, as in the appendicitis patient a Gram-negative infection is very likely, while in primary peritonitis a Gram-positive organism is probable. Ampicillin was the most commonly used antibiotic in this series, but with gradual changes in the pattern of coliform sensitivity it is less valuable and a cephalosporin or gentamicin may be preferred. Estimation of the serum level of the antibiotic is important in the severely ill patient to ensure that adequate blood levels are obtained but toxic levels are avoided.

Twenty-five years ago with the emergence of antibiotics it must have seemed that subphrenic abscess would be a subject on which the younger generation would have no experience. However, the present series indicates that subphrenic abscess remains a problem causing mortality and morbidity in the younger age group. The most effective action to decrease this problem further is for prompt diagnosis of acute appendicitis to be made in children and appropriate therapy instituted.

The cause and treatment of postvagotomy diarrhoea

JOHN R. CONDON, V. ROBINSON, M. I. SULEMAN, V. S. FAN
AND M. D. McKEOWN*

SUMMARY

Six patients with watery postvagotomy diarrhoea and 4 patients with intractable diabetic diarrhoea were treated with cholestyramine. The diarrhoea responded completely to therapy, during which the stool content of water, sodium, potassium and magnesium fell. Two of the patients, while receiving cholestyramine, had a rise in faecal fat, but this was not accompanied by diarrhoea, the stools being well formed.

Evidence is presented which suggests that the mechanism of diarrhoea is similar in both disorders and is due to division or neuropathy of the hepatic fibres of the vagus nerve. This results in distension of the gallbladder, contraction of which expels increased quantities of bile salts, which swamp the reabsorptive capacity of the small intestine and induce diarrhoea by direct action on the colon. If this theory is valid, cholecystectomy, by preventing large quantities of concentrated bile salts from suddenly entering the gut, may result in improvement of postvagotomy and diabetic diarrhoea.

VAGOTOMY accompanied by pyloroplasty or gastrojejunostomy is a frequently performed surgical procedure. It is sometimes complicated by diarrhoea which may respond to symptomatic medication or special attention to diet. Failure to respond to these simple measures indicates the presence of intractable diarrhoea, a most difficult long term management problem.

A series is reported of 6 postvagotomy patients and 4 diabetic patients with intractable diarrhoea which responded to cholestyramine, an anion exchange resin which binds bile salts in the gut. Our evidence suggests that the mechanism of diarrhoea is similar in both disorders, and a hypothesis is advanced to account for the change in bowel habit which may follow vagotomy.

Case reports

Case 1: A 58-year-old man had a truncal vagotomy and pyloroplasty in 1968 because of chronic duodenal ulceration. Division of the vagus was confirmed histologically and a postoperative insulin test showed no response to hypoglycaemia (blood sugar 21 mg/100 ml). Severe watery diarrhoea developed postoperatively but was controlled by codeine phosphate. However, the diarrhoea became progressively more severe and persistent, with 6–7 unformed stools daily, despite continuation of codeine therapy. Codeine phosphate was discontinued for 10 days before treatment with cholestyramine (4 g twice daily) was started. The diarrhoea stopped during cholestyramine administration but recurred when the compound was stopped; symptoms were recontrolled when therapy was restarted.

Case 2: A 57-year-old man had a partial gastrectomy in 1969 for a gastric ulcer. Eight months later he had a Heller operation for achalasia of the cardia, but 6 months postoperatively progressive dysphagia again developed. The stomach remnant and lower oesophagus were removed and a Roux-en-Y oesophagojejunostomy was performed. During this procedure a total vagotomy was carried out. Postoperatively the patient developed severe watery diarrhoea, 6–10 stools daily, there being little response of the diarrhoea to symptomatic treatment which was continued for 3 years. When cholestyramine (4 g thrice daily) was given the diarrhoea stopped, stools became well formed and their number fell to 1–2 per day.

Cases 3, 4, 5, and 6: Four subjects all had diarrhoea following vagotomy and pyloroplasty for chronic duodenal ulceration. The patients had 5–8 watery stools daily and there was poor response to symptomatic treatment in all the cases. Bowel habit and faecal appearance returned to normal in every patient when cholestyramine (4 g three times daily) was given. Diarrhoea recurred when cholestyramine was withdrawn but was recontrolled when the compound was restarted.

Case 7: A male aged 37 years had been a diabetic for 24 years. There had been evidence of peripheral neuropathy for 7 years and diabetic retinopathy for 5 years. Diarrhoea had been present for 16 years and was at first intermittent, lasting 3–5 days. The diarrhoea became progressively worse and at times there were 15–20 bowel actions per day, although 10 stools daily were the average. Investigations of the gastro-intestinal tract including three barium enema examinations were negative. There was no response to treatment with pancreatic extracts, codeine phosphate, antispasmodics, antibiotics, diphenoxylate and methylcellulose. Oral administration of cholestyramine (4 g thrice and later twice daily) resulted in a reduction of the frequency of stools to 1–2 daily, with 'solidification' of the faeces. Diarrhoea recurred when cholestyramine was withdrawn for two separate periods of time, but on both occasions the patient responded when cholestyramine was restarted.

Case 8: A 52-year-old man had suffered from diabetes mellitus for 25 years. There was marked evidence of peripheral neuropathy and diabetic retinopathy. Diarrhoea unresponsive to conventional therapy occurred 6–8 times daily. Cholestyramine (4 g twice daily) resulted in a reduction in bowel actions to once daily, the stools being well formed. Withdrawal of cholestyramine resulted in recurrence of diarrhoea until the drug was re-introduced.

Cases 9 and 10: Two diabetic subjects with evidence of peripheral neuropathy had had diarrhoea for 4 and 10 years respectively. There had been only limited control of diarrhoea with codeine phosphate. Cholestyramine (4 g once daily and later 4 g twice daily) reduced bowel movements to one per day.

Table I shows the faecal fat, sodium, potassium, magnesium and fluid contents of the stools in *Cases* 1, 2 and 3 when they were and were not treated with cholestyramine. In all the patients cholestyramine was suspended in water and drunk with the main meals.

Discussion

We have reported 6 postvagotomy and 4 diabetic subjects with intractable diarrhoea which responded to treatment with cholestyramine. Ayulo (1972) has also reported that patients with postvagotomy diarrhoea respond to oral cholestyramine therapy.

Postvagotomy and diabetic diarrhoea have many clinical features in common; in both disorders bowel movements are frequent and defaecation may occur without warning, the faeces may be watery in consistency and there may be steatorrhoea, delayed gastric emptying and disordered transit through the small intestine (Wruble and Kalser, 1964).

Complete division of the vagi results in enlargement of the gallbladder, which almost doubles its fasting volume and contracts poorly (Johnson and Boyden, 1952; Rudick and Hutchison, 1964; Inberg and Vuorio, 1969). Likewise diabetics are known to have large volume, poorly contracting gallbladders (Gitelson et al., 1963). A high incidence of gallstones is found following vagotomy (Reynolds, 1962; Nielsen, 1964) and also in diabetic subjects (Lieber, 1952). Furthermore, in both disorders examination of the gut has failed to reveal pathological changes to account for the diarrhoea, which is particularly resistant to therapy.

The almost invariable association of diabetic diarrhoea with visceral and peripheral neuropathy is highly suggestive of a neuropathy involving the vagus nerve, so that the mechanism of diabetic diarrhoea may be similar to that of diarrhoea following vagotomy.

The incidence of diarrhoea following truncal vagotomy can be reduced from 25 per cent to only 2 per cent by selective vagotomy, when the coeliac and hepatic branches of the vagus nerve are preserved (Johnston et al., 1972). These vagal branches supply the biliary system and pancreas. A disturbance of pancreatic exocrine secretion resulting in diarrhoea is, however, unlikely as neither diabetic nor postvagotomy subjects with diarrhoea usually respond to therapy with pancreatic extracts.

The fact that our patients with postvagotomy and diabetic diarrhoea responded to cholestyramine (an anion exchange resin which binds with bile acids) strongly suggests that in these disorders excess quantities of bile are reaching the colon. Increased quantities of bile acids have, in fact, been demonstrated in the faeces in postvagotomy patients (Allan et al., 1973a; Gerskowitch et al., 1973), and when individual bile acids are measured there is a highly significant increase in the excretion of chenodeoxycholic acid (Allan et al., 1973b). Saburov (1961) has reported increased bile flow in experimental animals when hydrochloric acid was introduced into the duodenum following section of the vagus. Secretin and other hormones may be involved in the stimulation of bile flow demonstrated by Saburov (1961). There is, however, no general agreement as to the effect of vagotomy, since Baldwin et al. (1966) have demonstrated decreased bile flow following vagotomy. Bile salt concentration is increased following vagotomy (Smith et al., 1973), and although the gallbladder usually contracts within 30 minutes of eating, resulting in a sharp rise in duodenal bile salt concentration (Sjovall, 1959), the concentration of bile salts in the postprandial aspirate is low following vagotomy (Fields and Duthie, 1965).

These facts suggest that gallbladder contraction is not in phase with gastric emptying, thus resulting in poor admixture of bile and chyle. Not only may there be poor admixture of bile and chyle but if the overall volume of the gallbladder is approximately twice normal (even in the presence of a mild defect of emptying) increased quantities of bile would pass into the gut. A high concentration of bile salts entering the small gut at inappropriate times could swamp the reabsorptive capacity of the ileum and enter the colon, partly undergoing deconjugation and resulting in diarrhoea (Sobotka, 1937). The probable existence of a limited reabsorptive capacity of the small intestine for bile salts can easily be demonstrated by feeding pure bile salts, when after a few days, severe diarrhoea results (Hardison and Rosenberg, 1967; Hofmann, 1968). Indeed, if free and conjugated bile salts are perfused through the colon, there is inhibition of absorption of sodium chloride, potassium and water (Mekhjian et al., 1971) and disturbances of colonic activity (Galapeaux et al., 1938), all features contributing to the resultant diarrhoea. Wingate et al. (1973) have also shown that conjugated dihydroxy bile acids inhibit electrolyte and fluid absorption and at high concentration evoke secretion of isotonic fluid in the jejunum. It has been suggested that this also contributes to the diarrhoea induced by bile salts (Low-Beer, 1973).

The only diarrhoea of known aetiology which responds to cholestyramine is that which occurs following resection or disease of the terminal ileum (Hardison and Rosenberg, 1967; Van Deest et al., 1968), when there is malabsorption of bile salts which enter the colon in excess (Row, 1967; Stanley and Nemchausky, 1967; Meihoff and Kern, 1968). Chenodeoxycholic acid is thought to play a major role in diarrhoea due to ileal resection (Poley et al., 1972), and Allan et al. (1973a b,) showed that increased faecal concentrations of this bile acid occur in patients with postvagotomy diarrhoea. These findings, taken in conjunction with the fact that patients with diarrhoea due to ulcerative colitis and idiopathic tropical sprue fail to respond to cholestyramine therapy (McCloy and Hofmann, 1971; Miettinen, 1971; Condon, 1973), are highly suggestive that postvagotomy diarrhoea is due to excess quantities of bile salts entering the colon. Furthermore, oral administration of cholestyramine, by binding bile salts and thus preventing their effects on the gut, resulted in a marked fall in fluid contents of the stool in the present series (*Table I*). The fall in faecal fluid was associated with a decrease in faecal sodium, potassium and magnesium, except in *Case* 3, in whom stool potassium rose.

In 1 patient the faecal fat fell, whereas in 2 other subjects (*Cases* 2 and 3) steatorrhoea occurred during cholestyramine therapy. Cholestyramine is known to induce steatorrhoea by binding bile salts, and it is of interest that the 2 patients receiving 12 g of the resin daily developed steatorrhoea (though not diarrhoea), whereas the patient taking 8 g of cholestyramine daily had a fall in faecal fat. The optimum dose of cholestyramine should therefore control diarrhoea and result in a fall of faecal fluid, fat, sodium, potassium and magnesium. Further experience of the use of the resin in our patients suggests that a dose of 2 g of cholestyramine twice to four times per day controls diarrhoea without inducing steatorrhoea.

We therefore propose that intractable diarrhoea in postvagotomy and diabetic subjects is due to surgical resection or neuropathy of vagal fibres which control gallbladder function. Increased quantities of bile salts are released into the small intestine, swamping its reabsorptive capacity. Diarrhoea is induced by a direct action of bile acids on the colon. The effect of bile salts, which inhibit intestinal absorption of water and electrolytes, can be counteracted by treatment with cholestyramine. If this theory is correct, then cholecystectomy, by preventing large quantities of concentrated bile salts from suddenly entering the gut, may result in improvement of postvagotomy and diabetic diarrhoea.

Possible parathyroid origin of gastrin in a patient with multiple endocrine adenopathy type I

J. CASSAR, J. M. POLAK AND W. M. COOKE*

SUMMARY

After removal of two large pancreatic insulinomas, although the presenting spontaneous hypoglycaemia was eliminated, severe and persisting haematemesis and melaena supervened with a rise in serum gastrin. The patient had multiple endocrine adenopathy (pituitary, parathyroids and islet cells), but no evidence of a pancreatic gastrin-producing tumour. After emergency gastric operation for the bleeding, the serum gastrin remained high until the hypercalcaemia and hyperparathyroidism had been corrected by subtotal parathyroidectomy. Immunofluorescence studies showed gastrin in the parathyroid tissue.

MULTIPLE endocrine adenopathy type I is characterized by tumours or hyperplasia of the parathyroids, pancreatic islets, pituitary, adrenal cortices and the thyroid gland (Ballard et al., 1964; Steiner et al., 1968). A patient with some unusual features and the results of special investigations are reported.

Case report

A 52-year-old Indonesian head teacher was admitted to Hammersmith Hospital in May 1973. She had noted enlargement of the feet since 1942. In 1963 she had become confused before breakfast and had had blackouts, preceded by cold sweats, when meals were delayed, and consequently had given up her job. She had been referred to a psychiatrist and found to be hypoglycaemic and acromegalic in 1965.

In 1967, in Paris, she had had cobalt radiation (3000 rad) to the pituitary gland. Frequent sweet drinks and injections of glucagon had also been advised because of continuing hypoglycaemic attacks. In February 1973, when diazoxide 150–200 mg per day had been started, she had had no further blackouts and her fasting blood glucose, which before treatment had been in the 30–35 mg/100 ml range, had risen to 112–120 mg/100 ml. One of her brothers and one of her sons had had renal calculi and another of her brothers may have had renal colic. Two of her children and one of her sisters were investigated at Hammersmith, and in each the fasting blood sugar, tolbutamide test, serum calcium and phosphate and skull X-rays were normal.

On admission the patient was obviously acromegalic, but further examination was unremarkable.

A tolbutamide test (*Fig.* 1) was started with the patient hypoglycaemic† (fasting) but symptomless, and was stopped after 60 minutes because she became drowsy. The serum insulin assays during both the tolbutamide test and an oral glucose test (*Figs.* 1, 2) showed fasting hyperinsulinaemia and grossly exaggerated serum insulin responses. The basal serum growth hormone level was high (68 μu./ml), and during the glucose tolerance test there was a paradoxical rise (*Fig.* 2). A ballooned sella was noted on X-ray of the skull. A pancreatic arteriogram (*Fig.* 3) showed a large vascular mass in the tail of the pancreas and another probable lesion in the body. Barium meal examination and liver scan were normal. At this time her serum calcium ranged between 11·8 and 12·5 mg/100 ml and the serum phosphate between 3·9 and 4·0 mg/100 ml. The serum alkaline phosphatase was 97–115 u./l. Plasma parathormone levels were 740, 790 and 990 pg/ml (normal <730 pg/ml). Plasma calcitonin was normal (<100 pg/ml). Gastric secretion was normal: basal acid output 2·1 mEq/h (normal < 5 mEq/h), peak acid output after pentagastrin 18·3 mEq/h (normal<30 mEq/h) and fasting plasma gastrin 200 pg/ml (normal<100 pg/ml). Thyroid-stimulating hormone response to thyroid-releasing hormone was normal and so were her luteinizing hormone and follicle-stimulating hormone responses to luteinizing-releasing hormone. Serum thyroxine was 90 ng/ml (normal 55–115 ng/ml). The plasma cortisol increased to 40 μg/100 ml in response to hypoglycaemia.

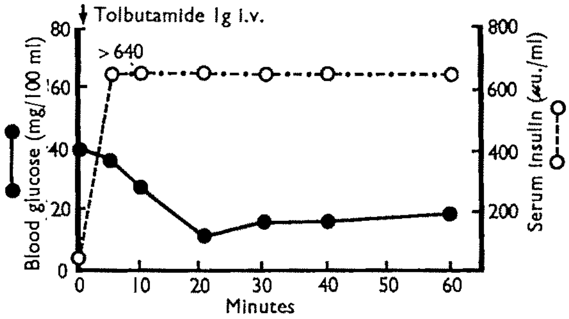

Fig. 1. Preoperative tolbutamide test.

At operation on 31 May 1973 (Professor R. B. Welbourn) a tumour approximately 10 cm in diameter was found in the tail of the pancreas and one about 3 cm in diameter in the body. The body and tail of the pancreas and the spleen were resected. One week after operation the fasting blood glucose was 155 mg/100 ml. Shortly after her discharge from hospital she was readmitted as an emergency with epigastric pain, haematemesis and melaena. She was shocked and her haemoglobin was 8·4 g/100 ml. Barium meal examination showed no ulceration and gastroduodenoscopy revealed no cause for the bleeding. The melaena continued and on 16 June a large bleeding ulcer in the first part of the duodenum was underrun and a truncal vagotomy and pyloroplasty carried out (Professor R. B. Welbourn). She was admitted yet again on 11 July with epigastric pain and melaena, when her haemoglobin was 6·4 g/100 ml. Endoscopy showed blood clot adherent to the posterior wall of the duodenum but no active bleeding. However, massive melaena continued and an antrectomy, with a Polya anastomosis, was done on 12 July (Professor R. B. Welbourn). Thereafter she had only minor epigastric discomfort and no further bleeding. The levels of gastric acid secretion and plasma gastrin are shown in *Table I*.

An air encephalogram on 26 September showed extension of the subarachnoid space into the pituitary fossa, implying some necrosis of her pituitary tumour, as suggested by a fall in the growth hormone level (7·9 μu./ml on 10 September). She was therefore treated with external radiotherapy (4000 rad) over 4 weeks, starting on 7 October. At the beginning of

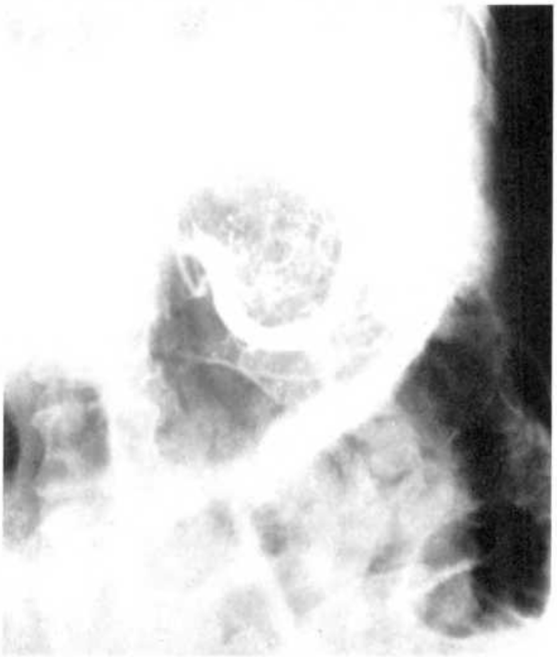

Fig. 3. Splenic arteriogram showing the abnormal blood vessels (surrounded by the splenic artery) of the insulinoma.

November she was still hypercalcaemic (12·1 and 12·4 mg/100 ml) and the urinary calcium excretion was 0·35 and 0·19 g in 24 hours.

She was thought to have hyperparathyroidism, and exploration of her neck on 18 December (Mr Selwyn Taylor) showed four enlarged parathyroid glands. The left upper and right lower glands were removed totally, and four-fifths of the other two were removed also. Recovery was uneventful and she had no further epigastric pain or discomfort. Two weeks post-operatively her serum calcium was 8·8 mg/100 ml.

On 1 February 1974 a glucose tolerance test (*Fig.* 2) showed normal glucose values, a normal serum insulin response and moderately raised serum growth hormone levels, although now reduced to about one-sixth of the pretreatment level of growth hormone. The patient was also symptom-free and she returned to her home country.

Table 1: GASTRIC SECRETION STUDIES AND SERUM GASTRIN LEVELS

Date	Surgery	BAO (mEq/h)	PAO_{PG} (mEq/h)	Fasting gastrin (pg/ml)

BAO, Basal acid output. PAO_{PG}, Peak acid output in response to pentagastrin.

Biopsies were processed for histological, cytochemical and immunohistochemical studies and for electron microscopy, as described previously (Pearse and Polak, 1974; Pearse et al., 1974). Both pancreatic tumours had the typical characteristics of an endocrine tumour with polygonal and round cells forming masses or glandular structures separated by bands of connective tissue and amyloid deposits. Histological methods for staining endocrine secretory granules (lead haemotoxylin, masked metachromasia, argyrophilia) were all positive. Ultrastructural studies revealed numerous electron-dense round secretory granules which were not identifiable as cell granules. Immunohistochemical studies were done with antisera against the following polypeptides: gastrin, glucagon, insulin, C peptide, secretin, calcitonin, growth hormone, adrenocorticotrophic hormone, GIP, VIP and motilin. Both tumours were reactive only to an antiserum against insulin, and the amyloid was reactive to an antiserum against porcine C peptide. The islet cells of the normal pancreas showed intense positive fluorescence for both insulin and C peptide, but weak reactivity for glucagon and no reactivity for gastrin.

The resected portions of the parathyroid glands weighed 1·24 g. There was diffuse hyperplasia affecting both chief and oxyphil cells. The latter were identified by the presence of numerous mitochondria (mitochondrion-rich cells) and contained electron-dense polymorphic secretory granules predominantly localized towards the vascular poles of the cells. Antiserum against human parathyroid hormone showed reactive chief cells scattered throughout all the glands and concentrated mainly around blood vessels. Most of the oxyphil cells were stained positively with an antiserum against human gastrin I.

The number and distribution of gastrin-producing (G) cells in the antrum were normal. G cells and other endocrine polypeptide cells were also present in biopsies of the duodenal and jejunal mucosa.

Discussion

Duodenal ulceration is common in multiple endocrine adenopathy type I even in the absence of a gastrinoma (Ballard et al., 1964). A barium meal examination before the first operation showed no duodenal ulceration, and it is a matter for speculation why haematemesis and melaena occurred soon after the distal pancreatectomy. Although the preoperative gastrin level was raised, the value after pancreatectomy, vagotomy and antrectomy was even higher. This is contrary to the usual fall after resection of the gastric antrum (Stadil, 1974). Thereafter the gastrin level fell steadily but returned to normal only after parathyroidectomy.

The source and cause of the marked hypergastrinaemia remain puzzling. Acute insulin-induced hypoglycaemia is a powerful stimulant of gastric acid secretion and gastrin release. Hypoglycaemic attacks produced by the insulinoma are unlikely to have caused the initial high gastrin value which was greater than that produced by the intravenous administration of insulin (Korman et al., 1971). Long standing chronic hyperinsulinaemia may well be very different. Under certain conditions insulin may inhibit gastric secretion (Spencer, 1973), and the coexistence of a duodenal ulcer and an islet cell tumour producing hypoglycaemia is rather unusual (Janowitz and Crohn, 1951). However, Ward and Welbourn (1961) showed that gastric secretion in a patient with an insulinoma was responsive to spontaneous hypoglycaemia.

Gastric acid secretion may be stimulated by the intravenous infusion of calcium, and recently Reeder et al. (1970) have increased plasma gastrin in this way in patients without the Zollinger–Ellison syndrome. Hypercalcaemia may have been responsible for the hypergastrinaemia in our patient, but if so the fall after antrectomy and prior to the parathyroidectomy is puzzling. An association between peptic ulceration, increased basal acid output and hyperparathyroidism with a return to normal basal secretion after parathyroidectomy has frequently been noted (Ward et al., 1964; Barreras and Donaldson, 1967; McGuigan et al., 1974). Dent et al. (1972) found elevated gastrin values in 8 out of 18 patients with hyperparathyroidism, with return to normal after surgery. Polak et al. (1971) have shown hyperplasia of the antral G cells in patients with primary hyperparathyroidism, but there was no such hyperplasia in our patient. The final normal gastric secretion test suggested that the parathyroidectomy had reduced gastric acid secretion, although part of this decrease may have been due to other factors including the reduction of the growth hormone level. There is evidence in man that gastric secretion is increased in acromegaly (Hall, 1971) and decreased in hypopituitarism (Smith et al., 1961) and after hypophysectomy (Dotevall and Westling, 1963). Growth hormone has been shown to increase gastric secretion to normal after hypophysectomy in rats (Kyle and Welbourn, 1956).

The finding of gastrin-like immunofluorescence in the oxyphil cells of the parathyroid is extremely interesting and suggests that these cells were the source of gastrin (Stremple and Watson, 1974). In the absence of direct measurements in the blood vessels supplying the parathyroid glands it is not possible to exclude absorption by the cells from the high level of circulating gastrin.

A gastrinoma could be another cause of the hypergastrinaemia, but despite a careful search there was no evidence of increased G cells in the antrum or duodenum or of a residual islet cell pancreatic tumour (although this cannot be excluded), and the plasma gastrin level eventually fell to normal. In spite of the increased serum gastrin, the preoperative gastric acid values were within normal limits. It is difficult to explain the rise in the basal acid output and the absence of a fall in the peak acid output after the pancreatectomy, truncal vagotomy and pyloroplasty. We failed to demonstrate hormones other than insulin, which may have had an inhibitory effect on gastric acid secretion, in immunocytochemical studies of the tumour.

The insulinoma showed characteristics typical of an apudoma (Pearse and Welbourn, 1973). The tumour reacted less strongly to an antiserum against insulin than is usual for insulinomas, but this fact and the presence of secretory granules uncharacteristic of beta cells have been well documented (Creutzfeldt et al., 1973). Amyloid is found in many endocrine polypeptide tumours and there is evidence that this apudamyloid is different from that found in secondary amyloidosis (Pearse et al., 1972).

Some acromegalics develop pituitary apoplexy spontaneously and an air encephalogram may show a partly empty sella and lowered growth hormone level, as in the present case. The air encephalogram after her operation showed extension of the subarachnoid space into the pituitary fossa with an empty sella. This is, of course, a sella partly empty because the tumour has shrunk, rather than a true empty sella syndrome (Neelon et al., 1973). Similar infarcts may well be precipitated by a series of shock states from gastric bleeds such as our patient suffered. Our patient early after her radiotherapy was still mildly acromegalic clinically and by serum growth hormone levels, but longer follow-up may well show considerable further late improvement (Gordon and Roth, 1973).

Acknowledgements

We wish to thank Professor Russell Fraser, Professor R. B. Welbourn and Mr Selwyn Taylor for encouraging us to publish details of their patient and for their helpful criticism of this report. We are grateful to Professor R. E. Steiner for the arteriogram, Professor

A. G. E. Pearse in whose laboratory the histochemical studies were made, Dr S. R. Bloom for the assays of gastrin, Professor W. Creutzfeldt for the donation of the antiserum to porcine C peptide and Miss S. Nichols for secretarial assistance.

Your hands are your most important instruments-
it pays to take care of them

The obvious fact that a urgeon's hands are of prime mportance to his work was orne in mind when 'Hibiscrub' vas formulated. 'Hibiscrub' is lesigned to keep hands healthy, ven after repeated use.

However, the prime mportance of a handwash is effectiveness: rapid prolonged bactericidal action against skin bacteria is assured by the presence of the well-proven antiseptic 'Hibitane'.

"These studies have shown that a 4% chlorhexidine detergent solution ['Hibiscrub'] is a potentially outstanding addition to the small list of detergent-disinfectant preparations for the hands of surgeons and nurses, with a greater immediate effect than that obtained with the hexachlorophane or even the iodophor preparations."
British Medical Journal, (1973), 1, 510.

The cholecystokinin test: an assessment

D. R. K. REID, I. M. ROGERS AND J. F. CALDER*

SUMMARY

A cholecystokinin (CCK) test was performed on 13 female patients who were thought to be having attacks of gallbladder pain and in whom at least one cholecystogram had been normal. In 10 of these patients the CCK test was performed during the course of a repeat cholecystogram in order to assess the effect of CCK on gallbladder contraction.

There was no constant relationship between a positive test and gallbladder contraction as measured radiographically.

Cholecystectomy was undertaken in 9 patients and of these, 4 had been CCK positive, 4 had been CCK negative and 1 had reacted equivocally. None of the CCK positive patients had stones at operation, whereas 2 of the CCK negative patients had one or two small stones. In this small series cholecystectomy relieved both the CCK negative and CCK positive patients of pain with equal frequency.

It is concluded that a negative CCK test by no means excludes the presence of symptomatic gallstones in patients with X-ray negative gallbladder pain.

PREVIOUS reports have shown that severe and recurrent gallbladder pain may be experienced when the cholecystogram is perfectly normal (Cozzolino et al., 1967; Valberg et al., 1971; Reid and Rogers, 1975). It is, however, not uncommon to find that the clinician will absolve the gallbladder as the source of the pain when the cholecystogram is normal and will undertake investigations designed to reveal pathology in other organs. Clearly a test which would confirm or refute clinical suspicion of X-ray negative gallbladder pain would be of considerable value.

Such a test was introduced in 1963 by Cozzolino et al. and is called the cholecystokinin (CCK) test. The test is stated to be positive when a typical attack of gallbladder pain occurs within 10 minutes of the intravenous injection of 1·5 Ivy units/kg of CCK. The value of this test has been assessed by several authors (Nathan et al., 1969; Valberg et al., 1971) and there is general agreement that in patients considered to have X-ray negative gallbladder pain a positive test will usually mean that cholecystectomy will relieve the attacks of pain whatever the operative or histological findings. However, there is no such agreement about the significance of a negative CCK test, although Nathan et al. (1969) made the unsubstantiated claim that about 40 per cent of patients with proved biliary disease are negative reactors. No positive CCK tests have been documented among patients used as normal controls (Cozzolino et al., 1963; Valberg et al., 1971).

The present small prospective analysis was designed to investigate further the significance of the CCK test in patients thought to have X-ray negative gallbladder pain.

Materials and methods

Thirteen female patients between the ages of 19 and 60 years who were thought to be having attacks of gallbladder pain despite a normal cholecystogram were studied. The duration of symptoms ranged from 8 months to 10 years.

Each patient had a CCK provocation test, and in 10 cases this was carried out during the course of an oral cholecystogram so that the effect on gallbladder contraction could be observed. In every case at least one normal routine oral cholecystogram had been obtained before the test was contemplated. The technique of the test was as follows.

The patients were told that they would be having another cholecystogram and that an injection would be administered to them during the X-rays. It was not suggested that the injection might provoke pain. Prone, prone-oblique and erect films were taken 14 hours after the ingestion of 6 tablets of iopanoic acid (Telepaque). Cholecystokinin/pancreozymin (Boots) was injected over a period of 1 minute and further prone or prone-oblique films were taken at 2, 4, 6, 8 and 20 minutes after the start of the injection. The injection of 1·5 Ivy units/kg of CCK was made into the tubing of an intravenous saline infusion set up behind the patient so that she was not made aware of the moment of injection, and the test was considered positive when typical pain was experienced within 10 minutes of the injection.

The decision about cholecystectomy was made on clinical grounds without reference to the result of the test although this information was not specifically withheld from the surgeon.

Results

Surgery was thought to be clinically indicated in 9 cases and cholecystectomy was carried out. There were 4 CCK positive and 4 CCK negative patients in this group and 1 patient had displayed an equivocal reaction (*Table I*).

CCK positive patients

It can be seen by reference to *Table I* that only one of the positive reactors was not relieved of her attacks of pain by cholecystectomy. It became clear after operation that there was a large functional overlay with this patient (Miss I. R.), but we decided to include her in the series since her initial presentation had appeared convincing. The remaining 3 patients

Mrs S. H.	23	10 mth; jaundice	±	NAD × 2	Mild chronic cholecystitis, a few cholesterol stones	Pain-free; 7 mth
Miss A. L.	26	3 yr	−	NAD × 2	Loculated gallbladder	Pain-free; 12 mth
Mrs G. G.	46	5 yr	−	NAD × 2	One cholesterol stone	Continuing pain; 4 mth
Mrs M. C.	49	1 yr; jaundice	−	NAD × 2	Mild chronic cholecystitis, 2 cholesterol stones	Pain-free; 12 mth
Mrs M. C.	36	11 mth	−	NAD	Chronic cholecystitis	Pain-free; 12 mth

* In 4 cases jaundice or dark urine and pale stools had occurred during one of the attacks of pain.
† The number of cholecystograms indicated includes the cholecystogram associated with the CCK test.
‡ Appendicectomy was performed during cholecystectomy.

Table II: DETAILS OF THE PATIENTS WHO DID NOT UNDERGO CHOLECYSTECTOMY

Case	Age	Duration of pain	CCK test	Cholecystography	Follow-up*
Miss A. M.	19	2 yr	−	NAD	Continuing pain; 1 yr
Mrs S. C.	37	1 yr	−	NAD	Lost to follow-up
Mrs C. P.	55	10 yr	−	NAD × 2	Pain-free; 4 mth
Mrs J. C.	39	2 yr	−	NAD	Continuing pain; 6 mth
Mrs G. M.	28	2 yr†	+	NAD‡	Continuing pain; 1 yr

* Follow-up was the period of observation after the initial presentation.
† Continuing pain after a previous cholecystectomy.
‡ Intravenous cholangiogram.

experienced immediate and complete freedom from pain after the cholecystectomy. On histological examination 2 of the gallbladders were normal, 1 showed mild chronic cholecystitis and 1 was loculated.

CCK negative patients

Three of the 4 negative reactors were similarly relieved of their pain by cholecystectomy (*Table I*). In one instance (Mrs M. C.) the CCK test was negative on the day before two small cholesterol stones were found within the gallbladder at operation. The patient not relieved of pain by cholecystectomy (Mrs G. G.) had one small cholesterol stone at operation, and it is conceivable that there is a residual small stone in the common bile duct to account for her continuing pain. On histological examination 2 of the gallbladders contained one or two small stones, 1 showed mild chronic cholecystitis and 1 was loculated.

The only patient with an equivocal CCK test had a few small cholesterol stones at operation and has had no postoperative attacks of pain (Mrs S. H.). In all the cases the gross appearance of the gallbladder at operation was normal.

Non-operated patients (*Table II*)

Cholecystectomy was thought not to be indicated in 4 patients because of the mild nature of their symptoms. All of these patients had been negative CCK reactors and had displayed a variable pattern with regard to pain during the period of observation. During the course of investigations a duodenal ulcer was revealed in one patient (Mrs J. C.) and this was treated by total truncal vagotomy and pyloroplasty. The attacks of pain, however, were typical of gallbladder colic and these were continuing when she was reviewed 6 months after the operation.

One patient (Mrs G. M.), who was not included in the series, presented 2 years after cholecystectomy for stones with what appeared to be typical biliary colic. Intravenous cholangiography was normal. The CCK test without X-ray control was positive and she continued to have troublesome colic during 1 year's observation.

Gallbladder contraction

Good gallbladder contraction in response to CCK was observed in only 3 patients (Miss M. M., Mrs C. P. and Miss I. R.). The other patients all showed only slight to moderate contraction. Only one case (Miss M. M.) showed a contraction as good as would be expected after a fatty meal.

Discussion and conclusions

It has already been established that gallstones may be expelled by passage through the biliary tree (Gray, 1974). Indeed, these 'disappearing stones' may account for a clinically significant proportion of patients who present with typical gallbladder colic but have a normal cholecystogram, and the patients in this series without stones at operation may be considered as possible examples (Reid and Rogers, 1975).

The significance of a positive CCK test

If we exclude Miss I. R. on the grounds of functional overlay then all the positive reactors were relieved of their pain by cholecystectomy. When stones are not present at operation we would suggest that the postoperative freedom from pain is because a stone-forming gallbladder has been removed.

The only other positive reactor (Mrs G. M.) had already undergone cholecystectomy and continued to have troublesome colic over 1 year's observation. One possible explanation for her pain would be a residual common duct stone.

There was some correlation between the clinical decision to operate and a positive CCK test in that all the positive reactors with a gallbladder *in situ* were in the operated group.

The significance of a negative CCK test

It is clear from consideration of the operated cases (*Table I*) that a negative CCK test does not absolve the gallbladder as the source of pain. Indeed, the yield of pathological abnormality was greater in the negative cases than that of the positive group and the postoperative freedom from pain was equally convincing.

No correlation could be found between the extent of gallbladder contraction and a positive test. This finding is at variance with that of other authors (Nathan et al., 1969) but is in agreement with the observations of Valberg et al. (1971).

It is concluded that the CCK test without further associated radiology may be a useful ward aid to diagnosis when the cholecystogram is normal. A positive test would tip the balance towards cholecystectomy. No real conclusion can be drawn from the negative test.

Acknowledgements

Two of our cases were under the care of Mr T. Menzies and Mr John Hutchison, Consultant Surgeons at the Royal Infirmary, Glasgow, and we are grateful to them for allowing us to report these cases.

Dr J. Duncan allowed us to use the services of the Radiology Department for the tests.

Intra-abdominal symptoms arising from spinal osteophytes

S. S. RAWAT, G. K. JAIN AND H. K. D. GUPTA*

SUMMARY

A case of abdominal pain caused by irritation of a segment of jejunum and another due to irritation of the ureter are reported. In both cases the cause of the irritation was established to be osteophytic growth from the 4th lumbar vertebra. After its excision the symptoms disappeared in both cases. To the best of our knowledge, osteophytes have not been reported before to be the cause of intestinal and ureteric pain, and it is therefore urged that in cases of intractable pain these must be considered as a possible cause.

It is generally accepted that spinal osteophytes do not by themselves produce any symptoms. However, they may produce symptoms when they become large enough to irritate the spinal dura mater, giving rise to a constant backache. Also, when an osteophyte enlarges sufficiently to compress a nerve, symptoms are produced. Pain can also result from the pressure of eroded bone on bone, but in these cases the osteophytes are not the cause of the local pain. The lateral bulges of osteophytes do not press on either the dura or the nerve roots and so produce no symptoms except those as a result of direct pressure on the sacrospinalis. It is commonly believed that the anterior growth of osteophytes does not produce symptoms for similar reasons.

The site of the spur, its size, the width of the canal and the amount of pressure determine the severity of the symptoms, while the segment of the cord or the nerve roots affected determine the symptom pattern. Local pain, radicular involvement, sensory changes, depression and absence of ankle and patellar jerks are the most commonly seen consequences. Intermittent claudication made worse by exertion is also seen. Sphincteric disturbances are, however, not common. Pressure on the trachea and oesophagus can produce symptoms, pressure on the vertebral artery may occasion cerebrovascular symptoms and spondylotic changes in the cervicothoracic spine may produce pain which closely simulates angina.

No reports have been found in the literature of cases in which symptoms were produced as a result of pressure of vertebral osteophytes on the ureter or intestine. Two such cases are presented here.

Case reports

Case 1: A 49-year-old Hindu female was admitted to the Dr S. N. Medical College Hospital, Jodhpur, on 12 December 1973 complaining of pain in the abdomen of 1½ years' duration. The pain was para-umbilical and of a dull aching nature. The intensity of the pain was worse after food. Occasionally the pain increased in severity and assumed a colicky character. These attacks were short, lasting an hour or so, and subsided without treatment. On examination there were three scars (result of branding with red hot metal) in the left para-umbilical area. There was deep-seated tenderness 2 cm below the umbilicus on the left side. In the same area a hard immobile mass 2 × 2 cm was palpable in close proximity to the vertebral bodies. No other abnormality was detected. The stools, urine, barium meal examination and fractional test meal were normal. A plain X-ray showed a sharp bony spur projecting from the upper margin of the 4th lumbar vertebra on its left side (*Fig*. 1). An intravenous pyelogram was normal.

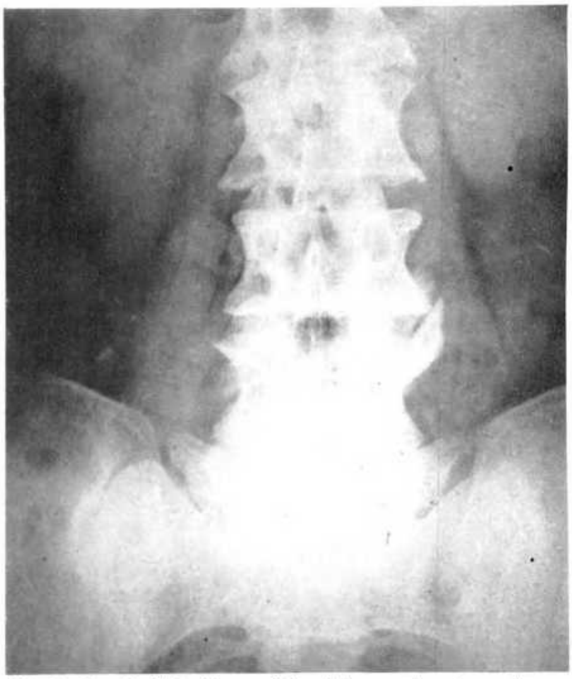

Fig. 1. *Case* 1. Plain X-ray of the abdomen showing a sharp bony spur arising from the upper left margin of the 4th lumbar vertebra. A lateral view was not taken as the condition was not suspected preoperatively to be responsible for the symptoms.

On 20 December the abdomen was explored through a midline incision. The stomach, duodenum, pancreas, gallbladder, colon and appendix were examined and found to be normal. The bony mass on the left side of the 4th lumbar vertebra was found to be projecting sharply anteriorly into the overlying posterior peritoneum. This part of the peritoneum was congested and opaque with scarring. On further examination the posterior aspect of a loop of jejunum 9 cm from the duodenojejunal junction was found to be congested and scarred. This part of the gut lay exactly over the projecting spur. The rest of the small gut was normal. The projecting spur was excised with a rongeur to make it flush with the posterior abdominal wall. The abdomen was closed in layers. The patient was discharged from hospital on 19 January 1974 after

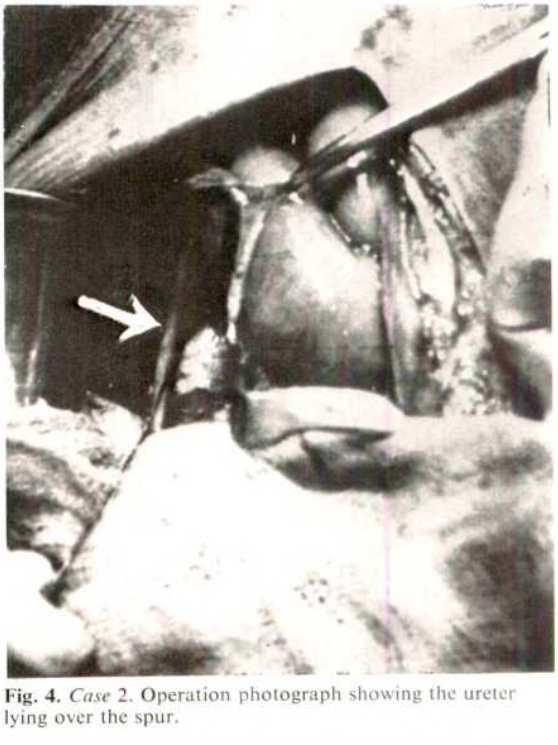

Fig. 4. *Case* 2. Operation photograph showing the ureter lying over the spur.

a 1-month observation period during which she made an uneventful recovery. She has remained symptom-free.

Case 2: A 59-year-old Hindu male was admitted to the Dr S. N. Medical College Hospital on 29 January 1974 complaining of pain in the left hypogastrium radiating to the left scrotum. The pain was constant and dull. Occasionally it became colicky, the colic lasting for about 2 hours in each attack. Physical examination revealed no positive findings. The left para-umbilical region was tender on deep palpation. The urine showed microscopic haematuria. Other laboratory investigations were normal. An anteroposterior X-ray of the abdomen showed osteophytic growth from the 4th lumbar vertebra on its left side. The lateral view showed the spur to be projecting anteriorly. Intravenous pyelography was undertaken to visualize the relationship of the ureter to the osteophyte. The lateral view showed the proximity of the spur to the ureter (*Fig*. 2). The ureter on the left side was lying over the spur; this corresponded with the tender area.

At operation the peritoneum over the spur was found to be scarred and the left ureter was stretched over the spur (*Figs*. 3, 4).

The surface of the ureter for a length of about 2 cm was congested. The anterior projection of the spur was excised with a rongeur. The peritoneum was stitched and the abdomen was closed. Postoperatively the patient was completely relieved of his symptoms and was discharged from hospital after a month's observation, during which he did not experience a recurrence of pain.

Conclusion

We do not suggest that all patients with ill-defined gastro-intestinal or urinary symptoms with spondylosis should be subjected to exploratory laparotomy. This would be a dangerous inference. We would, however, suggest that patients with vague symptoms and anteriorly projecting spurs should be further investigated with the view that such spurs may be the cause of the symptoms in some cases. A palpable spur is highly suggestive.

Tuberculous peripheral lymphadenitis in the Igbos of Nigeria

WILSON I. B. ONUIGBO*

SUMMARY

Peripheral lymphadenitis is a leading manifestation of tuberculosis. Among the Igbos, who constitute one of the largest ethnic groups in Nigeria, it presents most commonly in the neck, as in other parts of the world. An inguinal presentation, however, is also common. The nodes are often of considerable size. The maximal incidence occurs in the 10–29-year age group, males outnumbering females slightly. It is only in the 40–59-year range that tuberculosis is less common than lymphoma or carcinoma of the peripheral lymph nodes.

Of current concern in England and Wales is the high contribution to tuberculosis notifications from immigrants born in India, Pakistan and the new Commonwealth countries of Africa (Springett, 1972; British Thoracic and Tuberculosis Association, 1973). As reported, the immigrant population dominated in particular the pattern of non-respiratory tuberculosis, especially lymph node tuberculosis. Accordingly, this paper examines the pattern of lymph node tuberculosis from one of the African sources.

The Igbos, who constitute one of the largest ethnic groups in Nigeria (Basden, 1966), are the group studied. Their patterns of peripheral lymph node tuberculosis are compared with those reported recently from England (Hooper, 1972) and India (Krishnaswami et al., 1972).

The present study

One hundred and forty-two surgical specimens showing extrapulmonary tuberculosis were received in formalin at a central laboratory which serves the Igbos who live mainly in the East Central State of Nigeria. They were submitted by 59 doctors working at 5 government, 12 mission and 7 private hospitals during the period February 1970 to June 1974 inclusive.

Histological diagnosis of tuberculosis was based on the finding of typical granulomas with the full picture of caseation, epithelioid cells and Langhans' giant cells.

Analysis revealed 100 individuals with superficial lymph node tuberculosis and 42 with tuberculosis elsewhere (*Table I*).

Age and sex incidence

The age and sex distributions in this series are shown in *Table II*. It is apparent that the maximal incidence occurs in the age group of 10–29 years and that males outnumber females slightly.

Clinical presentation

Thirty-one out of the 100 cases of tuberculous peripheral lymphadenitis presented with a swelling in the neck alone or accompanied by only minor constitutional symptoms (*Tables III, IV*). This was the commonest single finding. It sharply contrasts with the paucity of tuberculosis in the submandibular, submental and tonsillar lymph nodes.

Fifteen cases (*Table III*) showed a particularly acute presentation, i.e. the so-called 'Asian tuberculosis' type. Of these cases, generalized lymph node tuberculosis occurred in 13, hepatomegaly in 7 and ascites in 2 patients.

Table I: SITE OF LESION IN 142 CASES OF EXTRAPULMONARY TUBERCULOSIS

Site of lesion	No. of cases
Superficial lymph node	100
Urogenital tract	17
Peritoneum	12*
Abdominal lymph nodes	8
Skin	5
Bone and joint	2
Soft tissue lesions without underlying bone or joint disease	1
Larynx	1

* Four cases showed peritoneal tuberculosis combined with lesions in the urogenital tract or abdominal lymph nodes.

Table II: AGE AND SEX DISTRIBUTIONS IN 100 CASES OF LYMPH NODE TUBERCULOSIS

Age group	Male	Female	Total
0–9	6	3	9
10–19	12	14	26
20–29	18	14	32
30–39	9	4	13
40–49	4	5	9
50–59	2	2	4
60–69	6	0	6
70+	0	1	1
Total	57	43	100

Inguinal lymph nodes were commonly involved. In addition to the 13 patients with generalized lymph node tuberculosis, 11 manifested the disease in the groin alone, 4 in both the groin and axilla and 3 in the groin and neck together. One case provided a possible clue to the genesis of inguinal lymph node tuberculosis by exhibiting the disease not only in the groin but also in the peritoneum.

Only 4 specimens were so disorganized by abscess formation that they were submitted as necrotic fragments. All 4 were from the neck. The remaining 96 specimens consisted of reasonably well-preserved single or matted nodes which measured from 1 to 7 cm.

Table III: SYMPTOMS AND OTHER FINDINGS

Symptoms and findings	No. of cases
Swelling in neck without other symptoms	25
Swelling in neck with mild general symptoms	6
Swelling in neck accompanied with chest symptoms	14
Swelling in neck with lymph nodes elsewhere affected	21
Acute presentation with high fever, hepatomegaly, etc.	15
Lymph node enlargement with non-lymphoid infection	5

Table IV: SITES OF INVOLVED NODES

Involved site:	No. of cases:
Cervical	56
Axillary	22
Inguinal	18
Submandibular	7
Submental	1
Tonsillar	1
Generalized	13
Unstated	1

Table V: CLINICAL DIAGNOSIS IN 28 CASES NOT DIAGNOSED AS TUBERCULOUS LYMPHADENITIS

Diagnosis:	No. of cases:*
Lymphoma	15
No diagnosis supplied	9
Filariasis	4
Salivary gland tumour	1
Neoplasm	1
Metastasis	1
Hyperplasia	1

* More than one diagnosis was given in some cases.

Of those reaching the considerable size of 3 cm or more, the sites were as follows: neck 15, axilla 10, groin 10 and submandibular region 1. The lateness of the presentation of such cases is well illustrated by the following case history.

Mr O. A., a tailor aged 26 years, first noticed bilateral swellings of the axilla, groin and neck in 1966. The left axillary swelling 'burst' in 1968. By August 1972 the increasing mass and pain in his left groin affected his trade by limiting his use of a pedal sewing machine! When biopsied in October 1972 the specimen consisted of two ovoid enlarged lymph nodes which measured 4·5 and 2·5 cm respectively in their longest axis. On section, the larger node was almost wholly caseous, while the smaller one exhibited scattered caseous foci. Tuberculous granulomas were seen in both nodes microscopically.

Clinical diagnosis

The provisional diagnoses in the 28 cases of this series which were not diagnosed as tuberculosis are listed in *Table V*. A comparison of the cases thought to be due to lymphoma, filariasis or metastasis gives some idea of how doctors rate these conditions among the lumps seen in Igboland.

Diagnostic peripheral lymph node biopsy presents a clear-cut picture of the causes of peripheral swellings in the Igbos (*Table VI*). Tuberculosis is the most common with 100 cases, while lymphoma outnumbers secondary carcinoma by 53 to 24 cases.

Discussion

The traditional therapeutical practices of the Igbos include surgical procedures (Onuigbo, 1955; Basden, 1966). Today, it is not uncommon to see multiple linear scars of lymphadenectomy on the neck, axilla and groin of patients who had consulted the traditional medicine man or 'dibia' at the start of their illness.

In comparison with both the English (Hooper, 1972) and the Indian (Krishnaswami et al., 1972) hospital series, the anatomical distribution in the present series conforms with world-wide patterns in one respect, namely, the predominance of cervical node affliction. It differs pointedly in the relatively high incidence of inguinal node infection. Since account was taken of the possibility of lymphogranuloma venereum, mycosis and other obfuscating diseases, is there a clue to the local prevalence of inguinal tuberculosis? In the present series non-lymphoid extrapulmonary tuberculosis was seen mainly in the peritoneum. It may well

Table VI: AGE DISTRIBUTION OF PATIENTS WITH TUBERCULOSIS, LYMPHOMA OR SECONDARY CARCINOMA IN 177 CASES DIAGNOSED AT PERIPHERAL LYMPH NODE BIOPSY

Age group	Tuberculosis	Lymphoma	Carcinoma
0–9	9	5	0
10–19	26	14	1
20–29	32	4	1
30–39	13	4	3
40–49	9	10	11
50–59	4	9	6
60–69	6	3	0
70 +	1	2	0
Unstated	0	2	2
Total	100	53	24

be, therefore, that the inguinal condition is merely the overt superficial sign of the underlying abdominal disease.

In the English series a node measuring 3 × 2 × 2 cm was cited to illustrate the fact that solid nodes may occasionally attain a considerable size. In the present study, much larger nodes were encountered commonly. They signify that patients present late for treatment and reflect the inadequacy of hospital facilities. *Fig.* 1 shows the distribution of hospital towns from which doctors sent specimens; their sparseness is self-evident.

The age incidence is of interest. In the Igbo series the maximal incidence was in the 10–29-year range, in contrast to the English series (20–39 years) and the Indian series (21–30 years). In other words, younger people are afflicted among the Igbos.

Kilpatrick (1969) pointed out that young people are examined in evaluating the prevalence of tuberculosis in a community and that in one such world-wide study Nigeria ranked sixth out of the 59 countries or areas surveyed. The relative frequency of tuberculous lymphadenitis in young people in the present series is in keeping with this high order of ranking.

The occurrence of tuberculosis in the elderly is also of some importance. In British communities the incidence of peripheral tuberculous lymphadenitis is increasing in the elderly but falling in other age groups (Peel, 1972). The Igbo pattern is probably still stable, for the incidence in the elderly is low.

Table VI shows that it is only in the 40–59-year range that tuberculosis does not outnumber lymphoma or carcinoma. When all age groups are considered the order of incidence in biopsied nodes among the Igbos is: tuberculosis, lymphoma and carcinoma. On the other hand, in the English series carcinoma ranked first and was followed by lymphoma and leukaemia, while tuberculosis came third. Thus, consonant with known epidemiological patterns (MacMahon and Pugh, 1970), the Negro Igbos suffer greatly from infectious diseases, notably tuberculosis.

Since the main theatre of the recent Nigerian civil war (1967–70) was in Igboland, is there any recognizable aftermath in the field of tuberculosis? The author's impression and that of other workers (Pust et al., 1974) is that tuberculosis has increased in the area. Unfortunately, no quantitative answer can be given because all the records which the author collected from 1963 to 1967 were lost during the war.

Acknowledgements

I am grateful to all the doctors who sent me their invaluable specimens and to my technical staff who processed them. I have had helpful discussions with visiting pathologists, especially Dr K. A. Misch and Professors C. V. Harrsion, G. M. Edington, E. O. Odunjo and A. O. Williams. Mazi Kalu Okorie of the East Central State Library Board helped me to locate the map of Igboland which was modified for this paper.

Gynaecomastia

D. B. HAMER*

SUMMARY

There are two different types of male breast enlargement—gynaecomastia and mammaplasia. A series of 53 consecutive patients with one of these conditions is presented. In the younger age group treatment has usually been conservative, surgery only being advocated when the diagnosis was in doubt or for cosmetic reasons. In the older age group the diagnosis must be confirmed histologically. The incidence of underlying conditions is much higher in this series than in any previously reported.

'GYNAECOMASTIA' is the term commonly used to describe male mammary hypertrophy. Its frequency is increasing because many different drugs are now being shown to be responsible for causing this condition.

There are two clinically separate types which will be referred to as 'true gynaecomastia' and 'mammaplasia'. *Gynaecomastia*: This is characterized by the appearance of well-formed breasts which are similar to those seen in the young adolescent female and are of a similar consistency. Prolonged oestrogen stimulation will produce this appearance (*Fig.* 1).
Mammaplasia: The second type consists of a subareolar plaque of tissue which is much smaller in size and freely mobile, not being attached to the skin or underlying tissues. It is discoid in shape with a regular edge and a rubbery consistency.

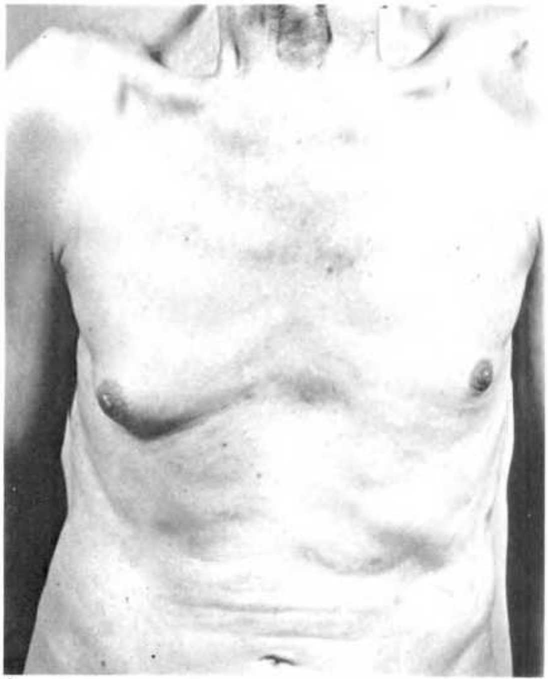

Fig. 1. Patient with oat cell carcinoma of the lung who developed unilateral gynaecomastia.

In mammaplasia or gynaecomastia, regardless of the aetiology, the microscopic findings are similar, with an increase in the ductal and connective tissue elements and no areolar or tubular formation. The pattern is similar to that in the pre-pubertal female breast (Bannayan and Hajdu, 1972).

Investigations

In view of the many underlying conditions a careful and complete examination is essential, with estimations of liver function, urinary oxogenic and ketogenic corticosteroids, biochemical screening, chest X-ray and blood count. The final diagnosis, as always, depends upon histological confirmation. The use of the drill biopsy is a useful adjuvant when, for example, a formal excision is not indicated but a diagnosis is required.

Analysis of the present series

This series consists of 53 patients who presented consecutively to the Breast Clinic at Hammersmith Hospital. There were 22 patients (42 per cent) recognized to be suffering from gynaecomastia while 31 (58 per cent) had mammaplasia. The age distribution was similar in both groups. These figures do not corroborate a previous report which maintained that 90 per cent of patients belong to the group defined as suffering from mammaplasia (Dexter, 1956).

Age distribution

The age at which the lesions developed is shown in *Fig.* 2. There is essentially one peak which lies between the ages of 10 and 30 years and includes the time of puberty. Only one case occurred in a prepubertal boy, thus confirming the rarity of this condition in this age group (August et al., 1972).

Laterality

Twelve patients (23 per cent) presented with bilateral breast enlargement (*Fig.* 2). In 16 (30 per cent) the lesion was on the right side, while in 25 (47 per cent) it occurred on the left.

Histology

The diagnosis was confirmed histologically in 37 cases; 31 by excision and 6 by high speed air drill biopsy under local anaesthesia. In 9 patients the lesion regressed without histological confirmation, 2 patients were considered too ill to undergo any extensive investigations, while the remaining 5 patients failed to reattend the outpatients' clinic after preliminary screening and were lost to follow-up.

---

* Department of Surgery, Hammersmith Hospital and Royal Postgraduate Medical School, London.

Associated conditions

In this series 25 patients (47 per cent) developed a mamary swelling without any obvious associated condition. Investigations in the remaining 28 revealed associations which in some cases were responsible for the condition while in others were probably coincidental.

Tables I and *II* list the patients in whom an associated condition was revealed.

Outcome

a. Conservative: Spontaneous regression took place in 9 patients while 5 declined to reattend, probably because the lesions had dispersed. In only one doubtful case was histological confirmation not possible because the patient was too ill to undergo any diagnostic procedure.

b. Surgery: An operation was indicated when the patient with an embarrassing cosmetic deformity which was not resolving requested excision or when the surgeon feared the possibility of malignancy. *Fig.* 3 indicates the patients requiring operation and the age distribution. Excision was carried out in 31 patients (58 per cent). Of these, 14 were suffering from gynaecomastia and 17 from mammaplasia. In the under 30 age group excision was required in 16 of 28 patients (57 per cent), while in those over 30 years of age 15 (60 per cent) required excision.

In all the cases the operation was performed under a general anaesthetic. Special care was taken to ensure that a complete excision was carried out, since a recurrence has been reported in a remnant of breast tissue (Gooel, 1944). Patients with a well-formed gynaecomastia required a submammary incision, while the smaller plaques seen in mammaplasia could be completely removed via a periareolar incision. The nipple was always preserved.

Discussion

The development of breast tissue depends upon the intricate balance of a number of hormones, the most important being oestrogens, progesterones, growth hormone and prolactin. The excessive production, defective excretion or the introduction of drugs which act directly or indirectly via their metabolites may stimulate breast proliferation and disturb this balance.

The observation that breast enlargement developing in the pubertal age group is associated with developmental changes in the size of the testes, penis and formation of pubic hair (Gangai et al., 1967) lends support to the theory that growth hormone is implicated. Three patients had testicular atrophy which is a well-recognized association (LeWinn, 1941; Treves, 1958).

After the Second World War, soldiers returning from Japanese prisoner of war camps developed gynaecomastia, both during their imprisonment and following release and the reintroduction of a normal diet; here again it is likely that an imbalance of hormones was responsible, and that growth hormone played a significant part (Jacobs, 1948). In this report it was shown that 10 per cent of these patients developed breast swellings and that 15 per cent of these subjects had a previous history of mammary enlargement occurring at puberty. Two patients in the present series gave a history of transient breast enlargement at puberty which subsequently recurred at the ages of 25 and 45 years respectively.

Many disorders have been implicated and, as would be expected, a variety of conditions in which there is hormonal imbalance has been shown to have a definite association. For example, hyperthyroidism and hypothyroidism (Wheeler et al., 1953; Becker et al., 1968; Ashkar et al., 1970; August et al., 1972), pituitary disorders (Treves, 1958), testicular tumours and testicular atrophy (Jacobs, 1948; Treves, 1958) and adrenal tumours and adrenal dysfunction (Nicolis

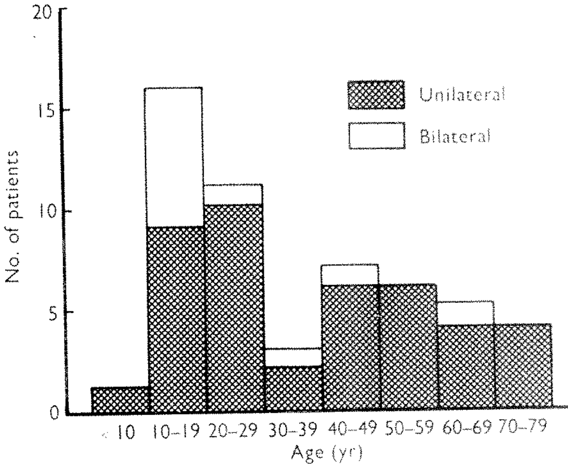

Fig. 2. Incidence of unilateral and bilateral mammary hypertrophy.

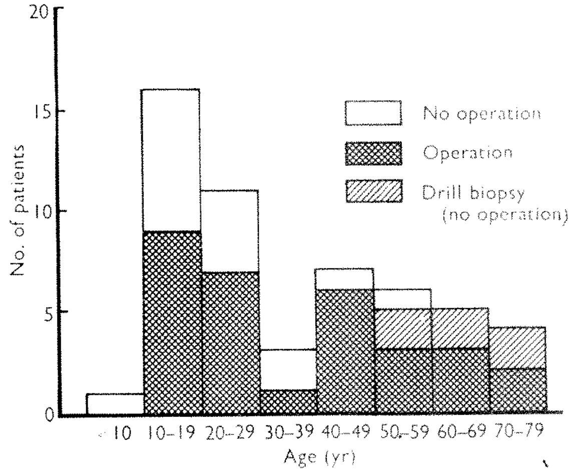

Fig. 3. Incidence of patients requiring operation.

et al., 1971). This problem can also occur in the presence of chromosome abnormality and it is well recognized in Klinefelter's disease (Jacobs, 1948; Wheeler et al., 1953).

Conditions which debilitate the body and upset the normal equilibrium may also cause gynaecomastia or mammaplasia. Disorders of liver function, malnutrition, prolonged immobilization, chronic chest conditions with or without hypertrophic pulmonary osteo-arthropathy, paraplegia, tuberculosis, diabetes mellitus, leprosy, chronic heart disease, hypertension and chronic renal failure are all well-documented causes (Jacobs, 1948; Wheeler, et al., 1953; Keddie and Morris, 1967; Lindsay et al., 1967; Margolis and Gross, 1967; Freeman et al., 1968a, b; Schmitt et al., 1968; Kaminsky, 1969). Male breast enlargement may present not only during the primary disease but also in the recovery period, for example, in malnutrition when refeeding is commenced or in patients with renal insufficiency when dialysis is begun.

In the present series 14 patients (26 per cent) had raised blood urea levels (> 40 mg per cent), pulmonary disease occurred in a further 8 patients and rheumatic heart disease in 3. Diabetes mellitus in patients treated

Table I: ASSOCIATED FACTORS IN PATIENTS WITH TRUE GYNAECOMASTIA

Case no.	Age of onset (yr)	Side	Blood urea nitrogen (mg %)	Associated condition	Associated drugs	Treatment
1	17	R L	—	Sickle cell trait	—	Nil
2	29	L	25	Grand mal	Primidone, acetazolamide, phenytoin, pheneturide	Excision

15	71	R	64	—	—	Excision
16	76	L	97	Obstructive uropathy	—	Excision

with insulin has previously been described, but of the 3 patients with this condition, one at the time of presentation was satisfactorily controlled by diet alone. The development of gynaecomastia or mammaplasia has not been previously reported after gastrectomy for peptic ulceration, but this was noted in 3 patients.

Many different medications have been associated with gynaecomastia, typically hormones, a variety of tranquillizers (chloropromazine, phenothiozines) and such compounds as spironolactone, amphetamines and digitalis (LeWinn, 1941; Clarke, 1965; Keddie and Morris, 1967; Margolis and Gross, 1967; Ginsburg, 1969; Turkington, 1972). In the present series digoxin had been administered in 5 patients, diuretics in 10 and 2 patients were on steroid preparations. Acetazolamide has not previously been indicated but 2 patients were taking this drug.

Hormones have not been used as a form of treatment in this series as has been advocated (Wernicke, 1939; Buirge et al., 1945), nor local irradication (Gangai et al., 1967; Wolf et al., 1969).

It is difficult to understand why this condition in many patients should be confined to one breast. A local susceptibility has been suggested and trauma has been implicated (Gooel, 1944; Greene and Howard, 1953; Treves, 1958). However, it is probable that trauma may bring the condition to the patient's attention and is not an aetiological factor. In this series no patient gave a history of trauma.

Patients over the age of 25–30 years should be thoroughly investigated and any underlying cause carefully excluded. The incidence of underlying factors is much higher in this series (53 per cent) than in any previously reported.

Acknowledgements

All the patients in this series were under the care of Mr J. Ian Burn and Professor R. B. Welbourn and I am grateful to them for their guidance and encouragement in the preparation of this paper.

Cavernous haemangioma of the frontal bone: case report

S. D. GUPTA, I. N. TIWARI AND N. K. PASUPATHY*

SUMMARY

A rare case of haemangioma of the frontal bone is presented together with a review of the literature. Carotid angiography was found to be a useful diagnostic aid to differentiate it from other lesions of the frontal bone. The best treatment is to excise both tables containing the haemangioma together with a rim of healthy bone in one block.

SKELETAL angiomas localized in a bone occur fairly frequently (Hitzrot, 1917; Anspach, 1937; Sherman and Wildner, 1961), but involvement of the skull bones, especially the frontal bone, is extremely rare. The first descriptions of a vascular tumour of the parietal bone appeared as early as 1845 and 1847 by Toynbee, but the first proved case of frontal bone haemangioma was reported by Mazzini and Brachetto-Brain as late as 1935. Since then very few solitary case reports have been added to the literature (Abbott, 1937; Keleman and Holmes, 1948; Wyke, 1949; Holmes et al., 1952). The present case is being reported because of its rare and interesting features and the pitfalls regarding its clinical diagnosis and management.

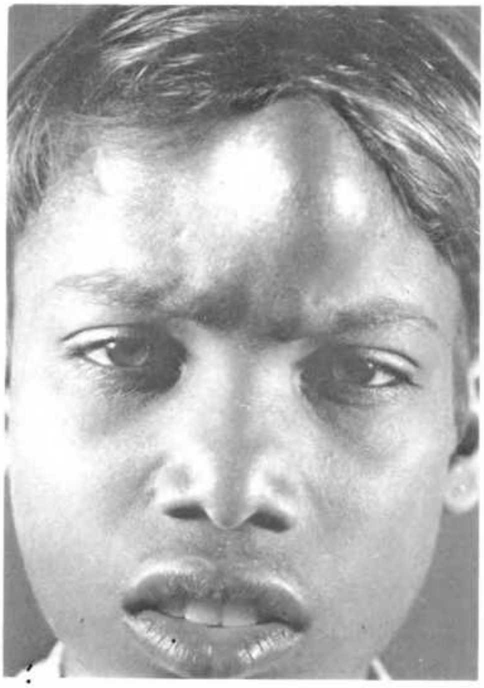

Fig. 1. Preoperative photograph of the patient.

Case report

R. a 13-year-old boy, was admitted to Jawaharlal Institute of Post Graduate Education on 20 March 1973 with the complaint of a gradually increasing painless swelling over the centre of the forehead of 8 years' duration (*Fig.* 1). There was no history of trauma or any symptoms suggestive of increased intracranial tension. On examination there was a hard bony swelling measuring 6 × 4·5 cm situated above the medial half of the right supra-orbital ridge and glabella. The skin over the swelling was normal and freely mobile. A vertical furrow with pulsation was felt over the centre of the swelling. There was a dilated pulsatile vessel running from the right temporal region to the upper part of the swelling. The patient had no neurological deficit. Cerebrospinal fluid findings, fundus examination and haematocrit values were normal.

An anteroposterior X-ray of the skull showed a very clear 'honeycomb' structure. Bony spicules arranged in a 'sun ray' pattern were seen on the lateral view. The outer table was replaced by the growth and the inner table also showed expansion and invasion (*Fig.* 2). A right carotid angiogram showed that the main blood supply of the growth was from a branch of the superficial temporal artery, and in the venous phase the dye was seen to diffuse into the superior sagittal sinus (*Fig.* 3).

At operation (May 1973) a forehead flap was made from one pterion to the other. An area of 2 cm surrounding the swelling was very vascular owing to the presence of many feeding vessels. Six trephine holes were made and interconnected. The inner table was lifted up from the dura mater, through which the feeding vessels emerged and then entered the haemangiomatous mass via the inner table. Both the tables containing the haemangiomatous mass with a rim of healthy bone were removed. The bony defect which measured 6·5 × 8 cm was bridged by split rib grafts. The cut sections of the specimen showed typical perpendicular striations filled with blood (*Fig.* 4).

The postoperative period was uneventful. The pathology report indicated a primary cavernous haemangioma of the bone (*Fig.* 5). The patient was followed up for a period of 6 months. The scar was well healed and the contour of the forehead was well maintained (*Fig.* 6).

Discussion and review of the literature

Though the incidence of skeletal angiomas forms 0·7 per cent and skull angiomas 0·2 per cent of all osseous tumours, frontal bone angiomas are still rarer (Geschickter and Copeland, 1936). Altogether 9 cases of frontal haemangioma have been reported in the literature in the past 100 years (*Table I*). Of the 9, only the last 5 cases have been proved. The lesion was reported as congenital in origin by Abbott (1937) and traumatic by Pilcher (1894), Mazzini and Brachetto-Brain (1935) and Wyke (1949). The present case had no history of trauma, as in the 4 cases reported by Kelemen and Holmes (1948) and Holmes et al. (1952).

There was nothing specific in the clinical findings except that the centre of the tumour was soft and pulsatile, as in those described by Zajaczkowski (1901). Wyke (1949) suggested that the radiological appearance of a 'sun ray' pattern is diagnostic of a haemangioma of the frontal bone as well as the findings of expansion and rarefaction of the bone without reactive

Table I: SUMMARY OF CASES REPORTED IN THE LITERATURE

Author	Age	Sex	Site in skull	Diagnosis	Surgery	Results
Pilcher (1894)	15	F	Frontal	—	Removed piecemeal	Not given
Eros (1928)	70	F	Right and left frontal	—	Died	Died
Mazzini and Brachetto-Brain (1935)	39	F	Right frontal	—	Removed	Not given
Abbott (1937)	3	F	Right frontal	—	Removed	Not given
Keleman and Holmes (1948)	35	M	Frontal	Preop. X-ray, biopsy	Outer table resected	Alive
Wyke (1949)	28	F	Left frontal	Preop. X-ray, biopsy	Both tables resected	Alive
Holmes et al. (1952)	54	F	Right frontal	Preop. X-ray, biopsy	Both tables resected	Alive
	52	F	Right frontal	Preop. X-ray, biopsy	Both tables resected	Alive
	45	F	Right frontal	Preop. X-ray	No surgery done	Alive

sclerosis. In the present case all these features were present except that some reactive sclerosis was also noticed, perhaps because the lesion was of long duration (8 years).

The first case of successful removal with recovery of the patient was reported by Pilcher (1894) who excised the tumour piecemeal. Zajaczkowski (1901) and Keleman and Holmes (1948) experienced problems of haemorrhage during the operation, postoperative meningitis and finally recurrence because they removed the outer table only. Therefore the best treatment is surgical excision of both tables containing the haemangiomatous mass together with a rim of healthy bone.

Acknowledgements

We are grateful to Dr M. Balasubrahmanyan, Principal of Jawaharlal Institute of Post Graduate Medical Education, Pondicherry, for allowing us to publish this paper. Our thanks are due to Dr N. P. Singh, Professor and Head of the Department of Anaesthesiology and Dr A. K. Bhattacharya, Professor of Radiology, for their cooperation in this work.

Reviews and notices of books

Operating Theatre Technique
Raymond J. Brigden, London. Third edition. 255 × 192 mm. Pp. 698+vii. Illustrated. 1974. Edinburgh: Churchill Livingstone. £12·50.

The Lewin Committee on Operating Departments reported in 1970, and in the past year there has been official action on its recommendation that non-nursing staff should be recruited and trained as skilled theatre technicians and scrub nurses. It is appropriate that this book should now appear in a third edition, ready to act as an indispensable and probably unique guide for those who train for these positions.

The first 280 pages are devoted to the design, equipment and management of operating theatres, to the work which goes on in them before and during operating sessions, and to the design of electrical, sterilizing and anaesthetic equipment. The information is notably up to date, and presented in an admirably clear yet detailed manner. There is a valuable glossary of technical terms.

There are over 500 illustrations, many being specially posed action photographs of high quality. The remaining 280 pages contain detailed lists and photographs of the instruments used in the main operations of general and specialist surgery.

One experienced theatre sister reported that she found this book 'highly readable and most interesting'; it is also good value for money. If kept in the theatre office it will be in constant use, both as reading for students and as a reference book for everyone.

PETER F. JONES

Gastro-entero-pancreatic Endocrine System. A Cell-biological Approach
Edited T. Fujita, Niigata, Japan. 260 × 163 mm. Pp. 195, with 154 illustrations. 1974. Stuttgart: Georg Thieme Verlag. DM.84.

The title of this book extends the view that hormones derived from the intestine and the pancreas form a continuous and overlapping system regulating the physiological functions of the gut. There are 18 chapters, all by Japanese authors, dealing with methods of identifying the specific cells of origin of the hormones and subsequently describing function. The book derives from a symposium held in 1972, and as such suffers from the inevitable lack of continuity. Nevertheless individual chapters are well written, usually with liberal references. Some chapters refer to experiments by the author published elsewhere, and this means that those with a special interest in this field will already be familiar with the results. For those not familiar with the field, the book is a good source of reference but is unlikely to live up to its title in providing a conceptual analysis of an integrated endocrine system.

C. G. CLARK

Pädiatrische Intensivbehandlung
V. von Loewenich and H. Koch. Pp. 142 with 61 illustrations. 1974. Stuttgart: Georg Thieme Verlag. DM.33.

This is a paediatric supplement to a previously published book on intensive care and intensive therapy by P. Lawin. This book discusses resuscitation of the newborn, the place of tracheostomy and long term endotracheal intubation. There are chapters on blood gas analysis and catheterization of the umbilical vessels as well as on oxygen therapy. Prolonged artificial ventilation of the newborn is discussed thoroughly and a special section deals with ventilator treatment in older children. The complications of ventilation treatment are fully discussed.

Prolonged recording of the various parameters of body functions, such as temperature, blood pressure, blood gas analysis etc., are discussed fully. Further chapters deal with acute renal failure and parenteral feeding.

The obvious omissions in this volume are neonatal surgery and the specific problems associated with conditions such as oesophageal atresia, intestinal obstruction and diaphragmatic hernia. It is unfortunate that the authors are working in a paediatric unit which has no direct access to specialized full time neonatal and paediatric surgery.

The book is well produced and contains numerous references but it is unlikely to be of particular interest to surgeons or indeed paediatricians whose knowledge of German is limited.

H. B. ECKSTEIN

Clinical Anesthesia, Monitoring in Anesthesia, Volume 9, Numbers 2 and 3.
Edited William H. L. Dornette. 254 × 175 mm. Pp. 428+xv, with 131 illustrations. 1974. Philadelphia: F. A. Davis Co. (Bristol: John Wright & Sons Ltd). £9·50.

Although there has been an intense interest in monitoring in the past decade it is still true to say that the type of monitoring employed is usually governed by the apparatus available rather than by the clinical importance of the measurement. For example, it is easy to record the ECG but difficult to monitor the cardiac output. Respiratory rate can be determined by many different methods but few instruments are capable of providing continuous and accurate measurements of expired tidal volume.

This unfortunate state of affairs is mirrored in this book. At first sight the list of contents is attractive. The book is divided into four parts dealing with fundamental considerations and pre-, intra- and postoperative monitoring. There are isolated chapters providing a good review of the topic ('safety in the use of monitoring equipment' and 'blood volume studies'), but on the whole the subject matter is descriptive and repetitive. Few authors attempt to define the problem, or to discuss ways in which it might be solved. The result is a multi-author 'cookbook' of monitoring techniques. It may be of some interest to the surgeon who has no previous knowledge of monitoring but it certainly contributes little to the state of the art.

M. K. SYKES

Advances in Surgery. Volume 7, 1973
Edited J. D. Hardy and R. M. Zollinger. 227 × 155 mm. Pp. 277+xiv. Illustrated. 1974. Chicago: Year Book Medical Publishers Inc. (London: Lloyd-Luke Ltd). £11·85.

This latest volume in a well-known series contains sections on the non-operative treatment of solid tumours, the management of colonic polyps, biliary-enteric fistulae, gastro-intestinal haemorrhage, tracheostomy and the surgical treatment of obesity. As would be expected in a volume of this sort, each section is written by experts and is full of information. The largest section is that devoted to gastro-intestinal haemorrhage, which contains a lengthy account of the use of arteriography in the diagnosis of this condition and its treatment by selective arterial infusion of Pitressin; the results reported are impressive, but the reader will look in vain for a balanced appraisal of the contribution of this technique to the problem as a whole, and indeed this whole section suffers from an excess of detail and lack of emphasis. The chapter on biliary-enteric fistulae is a valuable review of a rare condition. The remaining chapters are admirable informative reviews of important aspects of surgery, and in particular that on the surgical treatment of obesity is an excellent balanced discussion of a difficult and controversial subject.

All general surgeons will find something of interest and value in this volume, which should certainly find a place in all medical libraries.

L. P. LE QUESNE

Reviews and notices of books

Review of Medical Microbiology

Ernest Jawtz, San Francisco, Joseph L. Melnick, Houston, and Edward A. Adelberg, New Haven. Eleventh edition. 260 × 180 mm. Pp. 528. Illustrated. 1974. Los Altos, California: Lange Medical Publications. $8.50.

THE new edition of this popular book has been enlarged to include more basic science in order to appeal to medical students as well as to practising clinicians. Those who have long since left the laboratory for the bedside should, if they are interested, have no difficulty in understanding the clear and well-illustrated account of microbial physiology and genetics, mechanisms of immune response and modes of action of antimicrobial agents on microbes. An enormous amount of up-to-date information is to be found, including an account of oncogenic viruses.

The section on antimicrobial chemotherapy is especially useful in simplifying this complex subject and putting new drugs in their appropriate place. The book is dogmatic and without references to published work, but its contents would, in the reviewer's opinion, be accepted with only minor modifications by specialists in the very wide field covered.

For clinicians faced with an unfamiliar infection and little time to read about it, this book would give quick and reliable information.

E. J. STOKES

Arthroplasty of the Hip

Edited George Chapchal. 240 × 170 mm. Pp. 273+x, with 340 illustrations. 1974. Stuttgart: Georg Thieme Verlag. DM.78.

IN recent years there has been an increasing tendency for international surgical meetings to concentrate on a single theme. This volume shows how rewarding this can be. It is an edited report of the proceedings of the fifth international symposium on special orthopaedic themes organized in Holland. This symposium on arthroplasty of the hip was attended by surgeons from twenty-two countries. The participants are to be congratulated for having given as much time to consider the errors and problems of hip arthroplasty as to the successes achieved.

The proceedings have been edited into four sections: the first is concerned with biomechanical problems and the use of acrylic cement in total joint replacement; the second with the indications and contra-indications of various techniques of hip arthroplasty; the third section deals with difficulties and errors and the closing chapter the successes and failures. The symposium represents an excellent survey of the present state of our knowledge about arthroplasty of the hip joint on an international basis.

The volume is elegantly produced with clear diagrams and radiographs. British readers will especially thank the editor for having produced this volume in excellent English from papers which were no doubt originally given in half a dozen or more languages. We may anticipate with pleasure the further publication of the proceedings of subsequent international specialist meetings organized by our Dutch colleagues.

L. KESSEL

The Esophagus

Edited W. Spencer Payne and Arthur M. Olsen, Rochester, Minnesota. 240 × 160 mm. Pp. 339+xvi. Illustrated. 1974. Philadelphia: Lea & Febiger (London: Henry Kimpton). £7·60.

THE editors and the fourteen contributors of this book are all members of the staff of the Mayo Clinic and this book is a 'review of the Mayo Clinic experience with the esophagus and conditions affecting it'.

In order to prepare 'a relatively brief, readable yet comprehensive book' the editors state that they have tried to limit the bibliography. This has been achieved rather unevenly, and some chapters would benefit by the inclusion of reference to earlier workers. An account of the difficulties met with by the pioneers often makes it easier to understand the reason for adopting certain principles in management which are accepted today. This is, however, a very minor criticism. The whole layout of the book is excellent and the text and the illustrations are clear and helpful.

The anatomy and function of the oesophagus are described in a masterly way.

The diagnostic techniques are considered under three headings, 'Radiologic, Endoscopic and Physiologic'. A very clear evaluation is made of each particular method and this section is very helpful.

The techniques of oesophageal dilatation are discussed in detail, and great value is attached to the preliminary swallowing of a guide thread in suitable cases, the management of the chronic corrosive stricture by frequent bouginage using a guide thread is described and the occasional indications for surgical intervention are considered. The management appears to be very similar in principle to the 'auto-bouginage' advocated by Grey Turner and which has proved a safe and satisfactory treatment for many corrosive strictures.

The problem of reflux oesophagitis and hiatal hernia is described well and the management advocated is sound. It is refreshing to see conservative measures recommended in patients with a sliding hernia and with minimal symptoms. The less common para-oesophageal hernia always presents a potential hazard and operation should be considered in most cases. As regards the sliding hernia which requires operative treatment the value of Nissen's fundoplication is recognized.

Carcinoma of the oesophagus is discussed and the various methods of reconstruction are described. The editors, like the reviewer, conclude that in the majority of cases the 'stomach furnishes the quickest, easiest and safest method of reconstruction'.

All in all, this is a first class monograph in which the editors have managed to assemble a large amount of wise advice in a clear and readable manner. It should be read by all surgeons who practise oesophageal surgery.

R. H. FRANKLIN

Surgery of the Liver and Portal Circulation

William V. McDermott, Boston. 260 × 185 mm. Pp. 190+ix. Illustrated. 1974. London: Henry Kimpton. £6·65.

DR McDERMOTT is an international authority on liver surgery and particularly the surgery of portal hypertension. In setting out to produce a concise but comprehensive account of the subject he accepted a challenge which has frequently defeated the expert. In the event he has succeeded admirably. The book is beautifully written with excellent diagrams that enable the reader to follow with ease the investigations and treatments currently in use. The bibliography is well chosen and arranged in such a way that reference can be made quickly to classic articles or the subject can be explored in depth. There is just enough data in the chapter on liver transplantation for the postgraduate student in training or the general surgeon who wishes to remain informed. The book is excellently produced and can be recommended wholeheartedly to libraries or surgeons who want a concise but authoritative account of the present status of liver surgery.

J. H. PEACOCK

Surgery

R. M. Kirk, Willesden General Hospital, J. Maynard, London, and A. N. Henry, London. 250 × 195 mm. Pp. 384. Illustrated. 1974. Tunbridge Wells: Pitman Medical. Cased £5·50 (supplied); paperback £3·50.

THIS is a surgical textbook for the undergraduate student at the beginning of his studies. The book is written in a brief, easily understood manner. It contains sufficient information to enable the student to pass the qualifying examinations in surgery. The presentation of the subject is dogmatic, with the omission in most instances of alternative or controversial views. For this reason the book will be of little help to those working for higher surgical qualifications. The derivation of most medical terms is given, together with short biographical notes on famous people mentioned in the text. These add interest and colour to an otherwise rather dull presentation of the subject. Numerous clear line diagrams are used throughout which certainly help towards a full understanding of the brief text.

The book can be recommended to the undergraduate student.

A. B. BIRT

Current Medical Diagnosis and Treatment

Marcus A. Krupp and Milton J. Chatton, California. 260 × 180 mm. Pp. 1018 + xiv. 1974. Los Altos, California: Lange Medical Publications. £6·25.

THIS book is intended for the practising physician and not as a textbook of medicine. The chapters sometimes achieve this differentiation by tackling organ systems (e.g. the skin, the eye) from the point of view of symptoms, common causes and the approach to treatment. Other chapters are more formal in their approach (breast disease, nutrition). The difficulty with this arrangement is that in trying to provide a ready source of reference on diagnosis and treatment it succeeds in condensing a textbook of medicine and a textbook of therapeutics into a single (though sizeable) volume which may not provide sufficient detail for those who wish to consult it. There is much to be recommended in its therapeutic approach with the kind of advice on such topics as diet, care of the ischaemic foot and the treatment of haemorrhoids which is sometimes hard to find in general textbooks. The essentially didactic approach may well recommend such a book to students, but practitioners treating patients are likely to require much more information in dealing with specific problems.

There is little of surgical interest in this text, as is indicated by the title. Any book dealing 'primarily with internal medical disorders' can hardly discuss the surgical contribution to such disorders if the practising physician is to be sufficiently informed to advise his patients.

C. G. CLARK

Scientific Foundations of Surgery

Edited Charles Wells, James Kyle and J. Englebert Dunphy. Second edition. 278 × 215 mm. Pp. 838 + xix. Illustrated. 1974. London: William Heinemann. £15·50.

WHEN first published in 1967 the *Scientific Foundations of Surgery* was an ambitious concept and was very properly acclaimed. Unlike monographs, a standard work in medicine today—and at its inception this book bid fair to become so—has to provide a continuum of information. Seven years later we see the next stage in its growth; the editors, now with the welcome addition of Professor Dunphy, realize this responsibility, for the new edition is not a simple updating of previous material. The basis of the book has moved further towards science without prejudice to surgery, thus reflecting the very considerable change which has taken place in medicine in the past 7 years. Medicine is what this book is really about; those who read it will be ever more conscious that there are virtually no distinctions left between medicine and surgery—moreover this work is further proof that surgeons are very aware of this fact.

It would be tedious to categorize the realignment of chapters undertaken to bring about this change or the additional material; as would be expected, immunology has won a considerable place—just one example. The total number of contributors has changed very little. Nevertheless of approximately 130 names about half are newcomers; all are men of national and international repute, mostly from the United Kingdom and United States, with some from elsewhere. They have provided a substantial work in which the editors may rightly take pride.

BRYAN N. BROOKE

Basic Gastro-enterology

J. M. Naish and A. E. Read, Bristol. Second edition. 150 × 230 mm. Pp. 480, with 120 illustrations. 1974. Bristol: John Wright & Sons Ltd. £7·50.

THIS is a revised edition of a popular text. Though directed to gastro-enterologists as a primary text, the book appeals to undergraduates, for it is presented in a crisp, readable and easily assimilable style. It achieves its object of providing a sound basic text in an ever-expanding subject. The diagrams are particularly good, and also to be commended are the tables illustrating points in differential diagnosis.

Few textbooks qualify for a place in the personal library, but this one does, both for the teacher and the pupil.

C. G. CLARK

Essentials of Urology

D. E. Sturdy, Newport. 241 × 162 mm. Pp. 306 + vii, with 215 illustrations. 1974. Bristol: John Wright & Sons Ltd. £5·50.

THIS book was written by a general surgeon with a special interest in urology primarily for medical students, but perhaps it will also prove suitable for nurses or for FRCS candidates wishing to revise.

Previously the medical student could study either shorter sections on urology in surgical textbooks written by surgeons with no interest in urology or authoritative tomes in one or more volumes written by surgeons with perhaps too much interest in urology for the average medical student.

This book is concise, clear and well laid out. It is liberally illustrated with line drawings and radiographs.

The text gives a good comprehensive picture of the subject without going into too much detail or contentious argument. Perhaps at times it is too inaccurate; the classification of bladder tumours, for example, which should be accurate is not. Occasionally it is too accurate; total cystectomy, for example, is removal of the bladder but not the urethra or prostate. In general, however, the text is correct, up to date and easily understood.

The line drawings are excellent. There can be no better way of illustrating such a book. With the most minor exceptions—drawings of pyeloplasty copied from other textbooks instead of from the original descriptions, and a drawing of a ureter surmounted by a minute kidney depicting renal agenesis—all the drawings are extremely accurate. The radiographs, which never demonstrate as much when printed as they did on the viewing box, have been well chosen.

Undoubtedly this book fills a gap in the medical literature and, as such, will be welcomed by the medical student.

PHILIP CLARK

Chirurgie der Gegenwart

Edited R. Zenker, München, F. Deucher, Aarau, and W. Schink, Köln. 260 × 180 mm. Vol. 1, pp. 18, 14, 16 and 32. Vol. 4, pp. 51. Illustrated. 1974. München: Urban & Schwarzenberg. No price given.

FURTHER chapters have now appeared for this new multi-volume loose-leaf textbook on general surgery. A chapter by Gierhake on asepsis provides some useful basic information which all surgeons should know about. Other chapters deal with coagulation defects and the use of isotopes in diagnosis, and there is an extensive chapter by Carstensen on electrolyte disturbances. Other subjects dealt with include injuries to the vertebral column, surgery of the liver, reflux oesophagitis and other abdominal conditions.

All the chapters have an up-to-date list of references, and it would appear that once this work is completed it will become the major reference book in general surgery in the German language.

H. B. ECKSTEIN

The Doctor's Lawyer. A Legal Handbook for Doctors

Marc J. Lane, Chicago. 280 × 210 mm. Pp. 99 + xi. 1974. Springfield, Ill.: Charles C. Thomas. No price given.

THIS book, as the subtitle states, is a legal handbook for doctors. It is written by an American lawyer and most of the contents are only applicable to practice in that country. The tax laws are much more the province of the lawyer than the accountant in the United States and the author devotes a considerable part of the book to advice about obtaining maximum tax relief in one form or another. There are also sections on the legal aspects of medical partnership, profit-sharing pension schemes, and life and other insurance.

The only advice applicable to the British doctor is that on avoiding malpractice litigation. This is sound, clear and concise, and is written, like the rest of the book, in a racy style which is pleasant to read. Perhaps a second edition could have a British co-author, in which case the handbook would be very useful.

BERNARD LUCAS

Reviews and notices of books

Die vaginalen Operationen

Gunther Reiffenstuhl, Salzburg, and Werner Platzer, Innsbruck. 278 × 212 mm. Pp. 732 + xi, with 371 illustrations. 1974. Berlin: Urban & Schwarzenberg. No price given.

THIS atlas of vaginal surgery is the culmination of a combined effort by an anatomist, a gynaecologist and one of Austria's outstanding medical artists. The first section of the volume is devoted to the anatomy of the female genital tract and is illustrated by a series of exceedingly clear colour drawings which in themselves should be of great interest to all anatomists.

The majority of the volume is devoted to the various standard vaginal procedures which are performed in gynaecology, and these are described in great detail, not only in words but also with the same clear colour drawings. Each section draws particular attention to the pitfalls and mistakes which can be made and suggests how these can be avoided.

The authors do not attempt to evaluate the relative values of vaginal as contrasted to abdominal approaches to various conditions but aim simply to set out in detail the operative technique of the various vaginal procedures. There is no doubt whatever that this will become the standard work on vaginal surgery, and because of the clarity of many illustrations an extensive knowledge of German is not necessary to follow the context of this book. In view of the obvious cost of producing such a large number of really first class illustrations, one hopes that the publishers will decide to have the text translated into English so as to increase the potential readership considerably.

No price has been quoted for this volume, but in view of the standard of printing and reproduction the price is likely to be very high. In spite of this, the reviewer (who is no gynaecologist) feels certain that this volume is an unqualified success.

H. B. ECKSTEIN

Diseases of the Knee Joint

I. S. Smillie, Perthshire. 245 × 190 mm. Pp. 459. Illustrated. 1974. Edinburgh: Churchill Livingstone. £16.

HAVING read and respected Professor Smillie's classic on injuries of the knee for many years, one was eager to see how he had dealt with the numerous non-traumatic conditions which he must have seen. This contribution appears to be a combined textbook, monograph and patient vignettes, the latter being rather too frequent and detracting from the otherwise excellent observations. The reviewer was depressed to see such terms as 'patella alta', or even 'patella baja' being introduced into the world literature again. The chapter headings and divisions into such subjects as synovial affections, general or local etc., seemed rather unusual and restrictive. The pathological description of rheumatoid arthritis and haemophilla suggested that the author had not carried out this type of work in a 'combined clinic' setting. Quotations from other people's work in these fields were misleading and very few would accept their value, e.g. never use a tourniquet in haemophilla surgery, or Kessel's forage for Blount's disease or even the author's own technique of using Teflon membrane as an interposition barrier to limit adhesion formation after synovectomy.

However, the real mastery and authority appear in the chapters on osteochondritis diseases and on the amazing number of pathologies producing angular deformities around the knee at various ages, with their surgical correction. The illustrations are numerous and colourful and make this publication quite unique. Finally, the literature search has been extensive and industrious and for this reason alone this book is worth its place in a departmental library or on the book shelves of experienced orthopaedic surgeons.

R. B. DUTHIE

Book notices

[The Editorial Committee acknowledge with thanks the receipt of the following volumes. A selection will be made from these for review, precedence being given to new books and those having the greatest interest to our readers]

National Institutes of Health. Statistical Reference Book of International Activities Fiscal Year 1973
Prepared by International Co-operation and Geographic Studies Branch, Fogarty International Center. 110 × 190 mm. Pp. 52 + vi. 1974. Maryland: Department of Health, Education and Welfare. No price given.

Electrocardiograms: A Systematic Method of Reading Them
Michael L. Armstrong, Sydney. Third edition. 250 × 175 mm. Pp. 80, with 88 illustrations. 1974. Bristol: John Wright & Sons Ltd. £2.

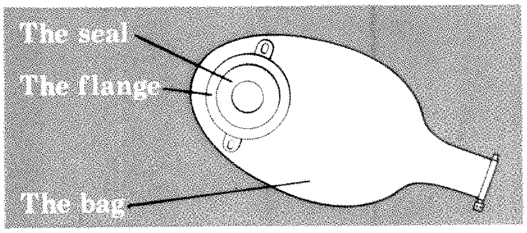
Benign Enlargement of the Prostate
K. E. D. Shuttleworth, R. W. Lloyd-Davies and Raymond Greene. 210 × 140 mm. Pp. 120 + vii, with 89 illustrations. 1974. London: William Heinemann. £4.

Environmental Health Perspectives. Experimental Issue No. 7 May 1974. Low Level Lead Toxicity and the Environmental Impact of Cadmium
260 × 195 mm. Pp. 323 + iv. Illustrated. 1974. Maryland: Department of Health, Education and Welfare. $12.15 p.a.

The continuing story of your successful ostomy

Good reasons why REDIFIT is the ostomy appliance for your patient.

Redifit will give added comfort and confidence to the Ostomist because it incorporates the following distinct advantages:



THE SEAL
The seal is of a superior Karaya gum which will not cause any irritation to the most sensitive skin. It will not distort, and will always create a perfect seal with the skin. It is less affected by extremes of temperature and humidity and so will always come to you in perfect condition.

THE FLANGE
This is a new pattern, unique to Redifit. It is not fastened directly to the bag but is held by a collar on which it can rotate. Therefore even after the bag is fixed in position, the angle of the flange can be adjusted to give the most comfortable position for the belt.

THE BAG
Redifit bag has no less than five laminations of plastic, and is guaranteed odour-proof for the normal life of the bag.
With only one layer of film, one cannot be sure of avoiding the embarrassment of escaping odour.

COMPETITIVE COST

Redifit for the special needs of special people

EDITORIAL NOTICES

Original articles or reviews are invited and editorial communications should be addressed to the *Editorial Secretary, British Journal of Surgery, c/o John Wright & Sons Ltd., Bristol BS8 1EX.* Articles are accepted on the understanding that they are contributed to this Journal only, and that articles and their illustrations become the property of the Journal unless the authors state, before publication, that they reserve the right to themselves. Each article should be accompanied by an adequate summary, suitable for publication. Authors are asked to ensure that original illustrations are securely packed and adequately protected.

BUSINESS COMMUNICATIONS should be addressed to *John Wright & Sons Ltd., British Journal of Surgery, Bristol BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery.*

BINDING.—Handsome Cloth Cases may be obtained for binding Vol. 60. Case, £2·00 post free; Case and binding, £7·50 post free. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers, who will also undertake the binding if desired.

ADVERTISEMENTS.—All communications should be addressed to *Hexagon Publishing Co. Ltd., 10 Spencer Street, St Albans, Herts AL3 5EG* (telephone St Albans 60641).

Instructions to Authors

PREPARATION OF MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

ILLUSTRATIONS AND TABLES

Illustrations should be clearly marked on their backs to show number, orientation and author's name. Explanatory legends should be typed on a separate sheet of paper accompanying the manuscript. For halftones, glossy photographs or positive prints (*not* X-ray negatives or slides) should be sent, unmounted wherever possible. When coloured illustrations are submitted as colour prints, they should be accompanied by the original transparencies where possible. As colour illustrations are expensive to reproduce, authors may be asked to make a contribution towards the cost. Drawings should be in a finished state suitable for reproduction. Any lettering should be large enough to withstand a reduction in size; sans serif lettering is recommended.

Tables should be typed on separate sheets of paper accompanying the manuscript. They should have an identifying number and a short descriptive heading. *All illustrations and tables must be referred to in the text.*

REFERENCES

The citation of references should follow the pattern shown in the Reference Citation Recommendations issued by the Medical Section of the Library Association. Copies of these recommendations can be obtained from the Secretary, Medical Section, The Library Association, 7 Ridgmount Street, London WC1E 7AE.

The name of the author and the date of publication are given in the text; the list of works cited is put at the end of the article, arranged in alphabetical order of authors' names. When references to two or more works by the same author are listed, they are arranged in chronological order. Where there are two or more authors (apart from the main author), these may be indicated in the text citation by the words 'et al.', following the name of the principal author; on the rare occasions when this may lead to confusion, the text citation should name as many of the collaborating authors as are necessary to identify the work cited. When several works published by the same author(s) in the same year are cited, they should be distinguished by the letters a, b, c, etc., placed immediately after the date.

In the list of works cited each reference to a *journal article* should give, in the order indicated, the names and initials of all authors, the year of publication (in parentheses), the title of the paper, the name of the journal (abbreviated), the volume number (in heavy type arabic numerals) and the numbers of the first and last pages of the article. Abbreviations for journal titles should be those adopted by *Index Medicus* since January 1971; where no abbreviation is given by *Index Medicus* the journal title should be left in full and the publishers will provide a suitable abbreviation. A reference to a *book* should give, in order, the names and initials of all authors, compilers or editors, the date of publication (in parentheses), the title of the book, the edition number (if other than first), the place of publication, the publisher's name and, where appropriate, the number(s) of the page(s) referred to. A reference to a *contribution to a book* should give, in order, the names and initials of all authors of the contribution, the date of publication (in parentheses) and the title

of the contribution; then, after the word 'In:', there should follow the name(s) and initial(s) of the author(s) etc. of the book, the title of the book, the edition number (if other than first), the place of publication, the publisher's name and the numbers of the first and last pages of the contribution.

Titles of papers and books should be given in the original language, with titles in Cyrillic and Greek alphabets transliterated.

Only in papers in which many and frequent references have to be made should the items be numbered; the numbers may then be inserted in the text without interrupting it with a list of names and dates.

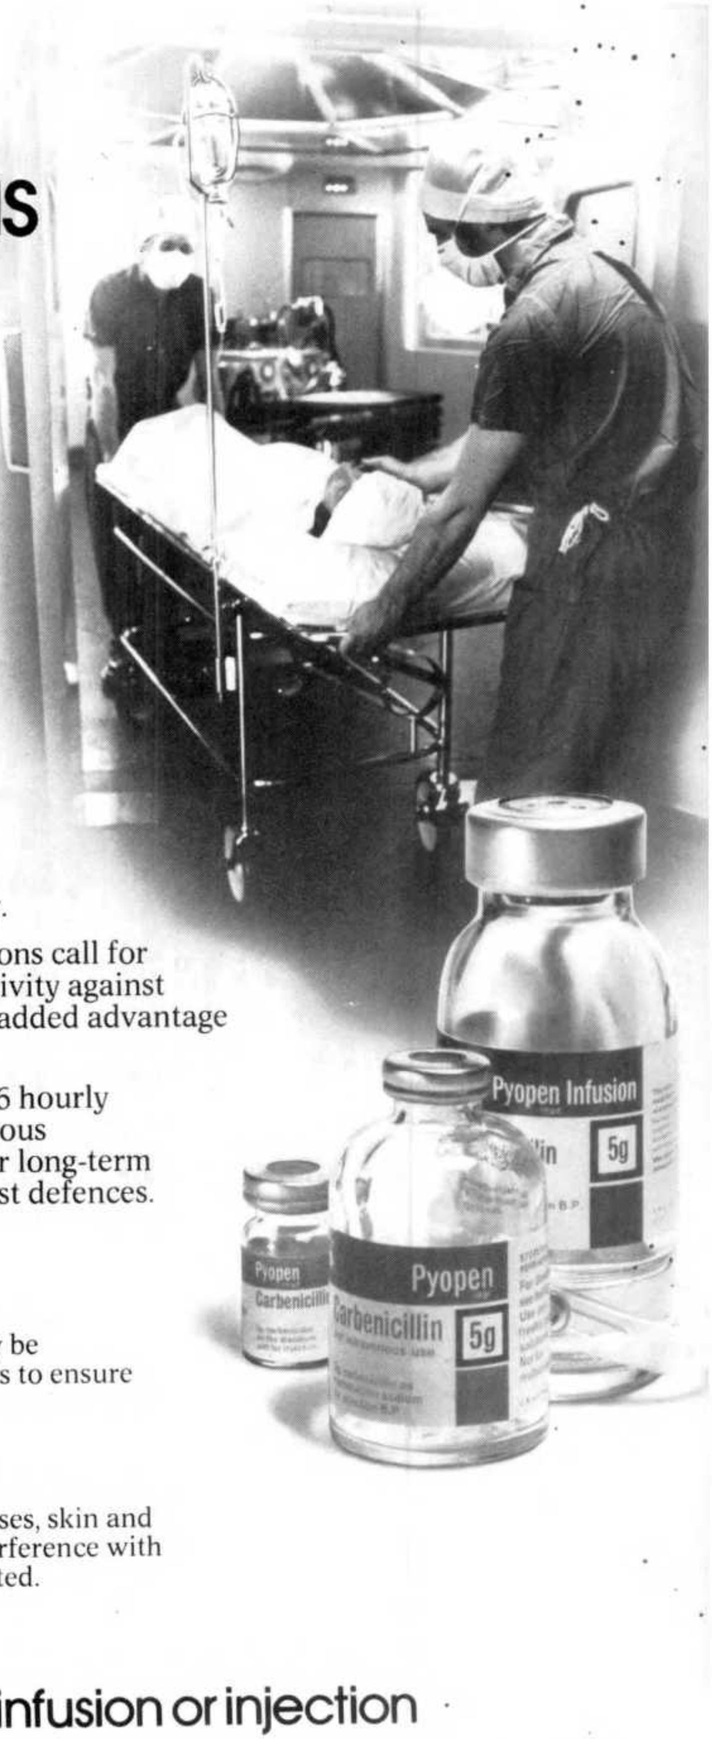
When pseudomonas threatens...



Pyopen

The skill of the surgical team,
hours in the theatre, the most advanced
techniques in the world . . . and infection
can still throw the outcome into jeopardy.

Systemic pseudomonas or proteus infections call for Pyopen. Only Pyopen offers you good activity against these Gram-negative organisms with the added advantage of penicillin safety.

Intravenous Pyopen, at a dosage of 5g 4–6 hourly will rapidly control many of these dangerous infections. And Pyopen is also suitable for long-term therapy and for patients with lowered host defences.

Adult Dosage
5g I.V. 4–6 hourly.
In patients with renal impairment dosage may be reduced; monitoring is advisable in these cases to ensure adequate serum antibiotic levels.
Contra-indication
Penicillin hypersensitivity.
Side-effects
As with other injectable penicillins. In rare cases, skin and mucous membrane haemorrhages due to interference with normal clotting mechanisms have been reported.

Pyopen–by infusion or injection

Further information is available on request.
Pyopen* (carbenicillin sodium B.P.) is a British product originated by
Beecham Research Laboratories, Brentford, England. *regd.

Our piggy bank could save your skin

Our Biological Skin Bank provides porcine skin dressings that have many advantages in the treatment of burns, traumatic skin loss, injuries, and soft tissue defects.

These temporary biological dressings dramatically reduce pain, inhibit infection, and reduce fluid and heat losses from the body. They protect exposed tendons, nerves and vessels and aid speedier recovery by allowing increased mobility; by promoting healing, and by improved formation of natural scarring.

The ready availability of the lyophilised Armour porcine skin dressings avoids the problems of obtaining homografts and now gives you an important new weapon in your efforts to provide a more rapid and satisfactory recovery for your patients.

ACM endoscopes leave nothing to the imagination

Most surgeons today recognise the superiority of endoscopy as a means of confirming diagnoses of colon diseases. It can be quicker and easier than laparotomy, and is also less traumatic for patients and makes fewer demands on hospital facilities.

The premier instrument for colonic investigations is the ACM F9L coloscope. Advanced features include 12X magnification and a sharp, wide angle circular image three times larger than competitive instrument's.

With it a surgeon can clearly view as far as the caecum, take biopsy specimens and perform polypectomies. After surprisingly little practice, coloscopy can be most rewarding. And the ACM coloscope is exceptionally easy to use – a single, one-handed joystick controls the poly-directional tip.

There's a shorter version, too, the F9S which will reach to the transverse colon and beyond. For the experienced coloscopist there's the dual channel F9A, a major operative, as well as diagnostic instrument.

a choice of fibre light source for every situation

TYPE 2150

. . . for the theatre

Solid state for greatest reliability, with infinitely variable light output from two 150 watt quartz halogen lamps. A heat filter is incorporated to reduce cable temperature and increase cable life. Housed in a robust steel case, making a compact unit, the fan is quiet, and lamp changing is a simple matter.

TYPE 175

. . . for outpatient Departments

Using a 75 watt high efficiency quartz halogen lamp with di-chroic reflector, the Type 175 incorporates a High/low switch which gives increased lamp life at low settings. Of robust steel construction, the unit occupies very little space, and the fan is quiet in operation.

stone stopping comments no.4

In a recent study[1] measurements of ^{47}calcium and of urinary calcium excretion were made in 125 cases of urolithiasis (78 solitary stone, 47 recurrent).

The authors found that 57 out of 60 patients with hypercalciuria showed raised absorption of ^{47}Ca, whereas 49 out of 106 patients showing similar hyperabsorption of calcium had *normal* calcium excretion. The authors concluded that "…a majority of stone formers, whether they are hypercalciuric or not, absorb calcium excessively from the intestine and this is more prevalent in cases of recurrent urolithiasis."

As a sequel to investigation 1, the same authors[2] studied the effect of Sodium Cellulose Phosphate on intestinal calcium uptake. In comparison to a low calcium, low oxalate diet; "Sodium Cellulose Phosphate can significantly diminish the absorption of calcium from the intestine; there is concomitant diminution of urinary calcium excretion. The plasma levels of the divalent cations do not appear to be influenced by this therapy."

Dosage in this study was varied to evaluate therapeutic effect. "Five grams reduced the intestinal calcium by as much as 85% and even a 1 g dose resulted in a 50% reduction… Such a dose (5 g), however, is probably essential when it is considered that the substance will ordinarily be dispersed throughout a semi-solid food bolus." Optimum administration time was considered to be 5 g t.i.d. at meal times, or within 1 hour after food.

In terms of side-effects and toxicity, the authors stated "Serum levels of calcium and phosphorus were not altered in any of the patients even when the substance had been taken for a period as long as 7 years in a dose of 5 g 3 times daily." There was no diarrhoea or intestinal disturbance, and patients found SCP reasonably palatable and easy to take.

Presentation

Whitish cream powder packaged in paper aluminium polythene single-dose sachets of 5 g each. Supplied in packs of 100.

Intra-arterial infusion of Solcoseryl: a clinical trial of a method of treatment for pre-gangrene of the lower limb

D. CHARLESWORTH, P. L. HARRIS AND M. K. PALMER*

SUMMARY

A randomized double blind trial of the drug Solcoseryl given by intra-arterial infusion was carried out on 57 patients with pre-gangrene of the lower limb. A sequential analysis was carried out and the trial stopped when the results showed a statistically significant result in favour of the active drug.

THE drug Solcoseryl has been shown to accelerate wound healing in rats and to facilitate healing of trophic lesions in patients with arteriosclerosis (Meythaler et al., 1963; Kappert, 1965; Hurlimann, 1970; Malaker and Sellwood, 1970; Kusztos et al., 1972). It is a protein-free extract of calf blood. The analytical data for the extract are known (Jaeger et al., 1965). Solcoseryl has been shown to increase oxygen uptake by liver slices by 200 per cent. It also increases oxygen consumption in substrate-saturated rat liver mitochondria. Its mode of action is not known but it has been suggested that it increases the rate of molecular transport of oxygen, which in turn allows faster rates of flow in capillaries (Dettli, 1973; Laszczower, 1973).

Seventy-five patients with peripheral vascular disease had major amputations of the lower limb at the University Hospital of South Manchester between 1967 and 1971. The average age of the patients was 69 years. One-third of the patients died in hospital following the operation and only a small minority were eventually able to walk on a prosthesis (Harris et al., 1974). The possibility that Solcoseryl might reduce the number of patients who required major amputations of the lower limb obviously merited careful investigation. We therefore carried out a randomized double blind trial of Solcoseryl in 57 elderly patients with pre-gangrene in the leg when the only alternative treatment was amputation.

Patients and methods

Patients with generalized arteriosclerosis who had pre-gangrene in the lower limb were considered for the trial. All the patients had a preliminary aortogram and only the patients for whom it was considered impractical to carry out reconstructive vascular surgery were included. In several patients previous direct arterial surgery had failed to reverse the ischaemic changes. All the patients had undergone a lumbar ganglionectomy on the ipsilateral limb at some stage prior to their inclusion in this trial. There were 57 patients in the trial; 15 were excluded from analysis for various reasons, the majority because the course of treatment was incomplete (*Table I*). Technical difficulties in placing and securing the catheter resulted in most of the failures in the early part of the trial. The average age of the 42 remaining patients was 69·7 years; there were 26 males and 16 females. Treatment was allocated at random by referring to pre-randomized lists; one for the patients with rest pain and the other for diabetics. Solcoseryl was supplied in ampoules, each containing 4 ml. Half the ampoules had red labels and the other half black; one contained the active drug and the other a harmless placebo.

Table I: NUMBER OF PATIENTS EXCLUDED FROM THE TRIAL AND THE REASONS FOR EXCLUSION

Reason for exclusion	Solcoseryl	Placebo
Technical failure	6	6
Adverse reaction	1	0
Intercurrent medical emergency	2	0
Total number excluded	9	6

An infusion of 200 ml of low molecular weight dextran (Dextran 40) was given through a small bore plastic catheter into the common femoral artery on the affected side. A small roller pump (Holter model 212) was used to propel the infusate into the artery and each infusion took approximately 1 hour to complete. Eight ml of the treatment drug were added to the infusate; red label ampoules to one group and black label to the other according to their allocation

Total	12	30	42

from the pre-randomized lists. The infusion was repeated each day for 10 days.

Treatment was considered to have failed if an amputation was carried out. In the patients who failed to respond to treatment amputation either was demanded by the patient or was suggested by the surgeon and accepted by the patient. The surgeon had no knowledge of whether the patient had been receiving the drug or the placebo. Follow-up of the successful patients was from 6 months to 2 years.

When a pair of patients with rest pain or a pair with diabetes had been treated, one with the active drug and the other with the placebo, their clinical results were made available to the statistician. The conclusion that either Solcoseryl was better or the placebo was better was plotted on a sequential chart by the statistician who was the only person who knew the code. If there was no difference between the responses the results for that pair of patients were ignored in the sequential analysis.

Results

The total number of patients who completed the course of infusions was 42. Thirty-eight patients were matched, giving 19 pairs; in the remaining 4 patients one of the pair failed to complete the course of treatment for technical reasons. Twenty-three patients received the active drug (average age 70·9 years) and 19 patients received the placebo (average age 68·4 years). All the patients had pre-gangrene in one leg. Twenty-eight of the 42 patients had frank gangrene; in the majority it was confined to one or two toes, and the total area of gangrene did not exceed 5 cm^2 in any of the patients. Eighteen patients in the Solcoseryl group had gangrene and 10 patients in the placebo group had gangrene. This disparity is not statistically significant ($\chi^2 = 2{\cdot}09$, $\nu = 1$, $P<0{\cdot}05$).

Nine of the patients in the Solcoseryl group and 9 of those in the placebo group had symptoms in the contralateral limb. The majority of patients had diffuse arteriosclerosis and a complete occlusion of the superficial femoral artery. Six patients in the Solcoseryl group and 5 in the placebo group had arteriographic evidence of occlusions in the tibial vessels (*Table II*). Four patients in each group had clinical evidence of a neurological deficit in the pre-gangrenous limb. The majority of patients had evidence of aorto-iliac disease and a superficial femoral artery occlusion. Both groups were similar in respect to the arterial lesions present.

Eleven of the 23 patients in the Solcoseryl group could walk before treatment began, compared with 11 of the 19 patients in the placebo group. The ratio of diabetic to non-diabetic patients was similar in each group: Solcoseryl, 8 out of 23; placebo, 7 out of 19. Because of the small number of patients the diabetic and non-diabetic patients were not analysed separately.

All the patients in the placebo group had an amputation of some kind (*Table III*). Only 14 patients in the Solcoseryl group had an amputation, and this difference is statistically significant ($P = 0{\cdot}004$, Fisher's exact test). One patient in the placebo group and 2 patients in the Solcoseryl group had a transmetatarsal amputation. All 3 of these patients could walk and were free from pain after an interval of 1 year. In patients who were not diabetic this was considered to be a successful outcome. If we consider the patients who had a local amputation and who were not diabetic as being successes, the figures are: Solcoseryl 11 successes, placebo 1 success, with a total of 30 failures (*Table IV*).

Eleven out of the 23 patients who received Solcoseryl had a result which was considered successful compared with only 1 out of 19 in the placebo group. This difference is statistically significant ($\chi^2 = 7{\cdot}17$, $\nu = 1$, $P<0{\cdot}01$). Patients who were admitted to the trial were also matched according to whether they were diabetic or not, and one of each pair received the active drug, the other the placebo.

Thirty-eight patients were successfully matched, giving 19 pairs, in chronological order of their entry into the trial, but 4 patients, all of whom received Solcoseryl, were without a match. Two of these 4 patients were 'successes' and 2 were 'failures'. In 9 of the 19 pairs the patient receiving Solcoseryl was considered to have fared better than the patient receiving the placebo. In the remaining pairs there was no difference. The probability of all 9 better results being for one treatment is $P = 0{\cdot}004$ (binomial test).

The results were plotted on a sequential chart as they became available (*Fig.* 1). It was decided that the superiority of the active drug would be accepted only if the probability of a positive result occurring by chance alone was less than 0·01. The level of statistical significance was fixed at 1 per cent before the trial began because the treatment was considered likely to be uncomfortable to the patient and to carry a risk of infection.

Discussion

The two groups of patients in this trial were well matched and sequential analysis shows a statistically significant result in favour of Solcoseryl.

There is evidence to suggest that a lumbar sympathectomy done for intermittent claudication does not influence the rate of amputation in patients who subsequently develop pre-gangrene (Bloor, 1961). Most surgeons, however, perform a lumbar sympathectomy in the circumstances we were considering, and approximately half the patients can be expected to improve (Taylor and Calo, 1962; King et al., 1964; Szilagyi, 1967). All the patients in this trial had had a lumbar ganglionectomy on the ipsilateral side at some time before the trial began. Consequently, whatever the mode of action of this drug, it is unlikely to mimic the effects of a lumbar ganglionectomy.

In the placebo control group we infused low molecular weight dextran, which could be expected to improve capillary infusion by reducing viscosity, rather than use a peripheral vasodilator. There is evidence that peripheral vasodilators do not benefit patients with peripheral vascular lesions and there is no reliable evidence to suggest that they do (DeBakey et al., 1947; Coffman and Mannick, 1969; Richards, 1970; Coffman, 1971.)

We concluded that in patients with severe peripheral ischaemia due to arteriosclerosis, Solcoseryl given by the method we describe may help to avoid a major amputation.

Acknowledgments

We wish to thank Dr M. Laszczower of Solco, Basle, for providing the drug and Mr J. Howat and Mr R. Jones for their help with the trial.

Extended deep femoral angioplasty : an alternative to femoropopliteal bypass

L. T. COTTON AND V. C. ROBERTS*

SUMMARY

The results of extended deep femoral angioplasty (EDFA) have been analysed for 74 legs in 72 patients. In 69 per cent a femoropopliteal bypass would have been possible, so EDFA is considered here as an alternative operation. The success rate was 66·9 per cent, the failure rate 25·6 per cent and no effect was achieved in 7·5 per cent. Diabetes adversely affected the results. Of the failures, 45 per cent were diabetic, while the incidence of diabetes was only 14 per cent in the group where the operation was successful. The long term results of the operation were reasonable, 75 per cent being successful for 10–39 months. Age had no bearing on success or failure.

The effects of EDFA were most dramatic on intermittent claudication. In 52 per cent it was abolished and in 92 per cent claudication distance was increased to over 200 yards. Good results were achieved after failed lumbar sympathectomy and failed femoropopliteal bypass.

Successful results of EDFA could be predicted best by inspection of angiograms. Success or failure could have been predicted from the state of the run-off in 81 per cent of the cases. Claudication and rest pain were the most relieved by EDFA, followed by ischaemic ulceration of the leg. Gangrene of digits was helped but less than had been hoped.

We conclude that the indications for femoropopliteal bypass are limited to cases of digital gangrene where angiography shows that bypass is possible or where an EDFA operation has failed.

In February 1973 we produced a preliminary report on the operation that we described as 'extended deep femoral angioplasty' in a group of 34 patients suffering from claudication, rest pain and gangrene due to atherosclerotic disease sited below the level of the inguinal ligament (Berguer et al., 1973). Credit must be given to Martin et al. (1968) who showed the effectiveness of revascularization of the leg by opening up the orifice of the deep femoral artery. Our contribution, first reported in 1971 (Cotton, 1971) and independently by Martin et al. (1972), has been to show how extension of the angioplasty down to the first, second or third bifurcation of the deep femoral artery is even more effective. It must be stressed that the operation of EDFA means that the deep femoral artery must be mobilized and patched very extensively for as much as 15 cm of the main trunk of the deep femoral artery. In all the 'run-in' was considered satisfactory as judged by a good femoral pulse and a satisfactory filling of the aorta and iliac arteries in aortograms. This present paper analyses our further experience in a total of 74 EDFAs performed over a period of 44 months from April 1970. Before our description of this operation the operation of choice was a femoropopliteal bypass graft using an autogenous vein, the reversed long saphenous vein. EDFA has, in our experience, become the first operation to be tried for most cases of ischaemic disease below the level of the inguinal ligament.

We believe many vascular surgeons, especially in Great Britain, have performed fewer femoropopliteal bypass operations in recent years for a variety of reasons. The operation has an immediate failure rate of at least 3 per cent. At 5 years the patency rate has reduced to 61·5 per cent (Baddeley et al., 1970). In addition, the long saphenous vein may be too narrow to achieve a satisfactory bypass or there may be no vein available because it is varicose or may have been removed in a stripping operation. We believe that EDFA is the first operation of choice for the treatment of most cases of femoropopliteal disease due to atherosclerosis.

The operation of extended deep femoral angioplasty

The details of the operation of EDFA have been described previously (Berguer et al., 1973). We have since introduced a major modification in *omitting the endarterectomy*. The operation we now perform is a simple incision of the common and deep femoral arteries to a point in the deep femoral artery where the vessel is reasonably free of disease, being soft and pliable. This may be as far down the artery as 15 cm from its origin. A vein or more often a Dacron patch is sewn into the deep femoral and common femoral arteries, the aim being to double the cross-sectional area of the deep femoral trunk. The main advantage of the omission of the endarterectomy is the avoidance of the possibility of intimal flap dissection at the distal end of the endarterectomy. Its omission greatly simplifies and shortens the operation. In our experience it has replaced the need for common to deep femoral artery autogenous vein bypass grafts (Berguer and Cotton, 1973).

Results

The results of 74 EDFA operations have been assessed in 72 patients (*Table I*) over the period from 1 April 1970 to 31 December 1973. A good result is shown by relief of claudication and rest pain and by the healing of gangrene either naturally or after minor amputation. Partial success means immediate relief of claudication and rest pain followed by the return of symptoms of ischaemia after an interval of some months. Failure of the operation was usually followed by a major amputation, though a few limbs were saved by femoropopliteal bypass. No patient operated on for claudication alone came to amputation.

---

* Department of Biomedical Engineering, King's College Hospital Medical School, London.

Good results (44 legs)
In this group (*Table II*) severe claudication (42 cases) and rest pain (34) were the commonest complaints. Gangrene of the toes (5) was less common. Ischaemic ulcers (6), sited at the malleoli, on the dorsum of the foot or on the heel, benefited from the operation. Two EDFA operations were successful after failed lumbar sympathectomy and 4 were successful after clotting of a femoropopliteal bypass graft.

Partial success (5 legs)
The operation was a success for a period of months after which rest pain returned. In 3 cases a lumbar sympathectomy was successful in relieving symptoms at intervals of 4, 5 and 6 months respectively after the primary operation. A remission of ischaemic symptoms has been prolonged in these cases over 9, 24 and 30 months respectively. In one case, following a failure of femoropopliteal bypass, a patch angioplasty was successful for only 1 month, following which a lumbar sympathectomy has relieved symptoms for a period of 30 months. In the last case the angioplasty was successful for a period of a year, when symptoms returned, necessitating a major amputation.

Failures (20 legs)
Twelve patients came to a major amputation. In one, failure was precipitated by rupture of the vein patch on the fourth postoperative day. Three legs were saved by femoropopliteal bypass. Five patients died; one from haemorrhage which was a direct result of the operation. The other deaths were due to cerebral haemorrhage, coronary thrombosis, bronchopneumonia and renal failure. The incidence of diabetes was 45 per cent in the failed cases and 14 per cent in the successful cases.

No change (5 patients)
This was the disappointing group. The patients were all claudicants and none would admit to any improvement in claudication distance. Their follow-up extended for a period of 12–40 months. All could have had a bypass operation but only one volunteered for a second operation—a vein bypass from the external iliac to the deep femoral artery which was successful. In this case it was not appreciated until after the EDFA operation that there was a degree of iliac artery stenosis. Once this was corrected the EFDA operation succeeded.

Duration of follow-up
The duration of follow-up in the successful cases is shown in *Table III*. The longest period of follow-up is 41 months. Thirty-three of the 44 limbs have remained satisfactory for periods from 10 to 39 months. Five-year patency rates have yet to be realized before the results of this operation can be compared with those of femoropopliteal bypass.

Table I: RESULTS OF EDFA

FPBP, Femoropopliteal bypass.

Effect of EDFA on claudication
This proved better than had been expected. We had not thought it possible to improve claudication by merely

widening the trunk of the deep femoral artery, and yet, as can be seen in *Table IV*, there was a striking improvement in claudication distance. In the 44 successful cases claudication was completely relieved in 23 (52 per cent). In 92 per cent a claudication distance of more than 200 yards was achieved. In only 3 cases claudication distance was still limited to 100 yards.

Age and success

In *Table V* the association between age and success or failure is summarized. The numbers are small but it does not seem that there are significant differences between the two groups. Certainly it does not appear that younger patients fare less well than the aged.

Angiography and success and failure

Angiograms were available for analysis in 57 patients. They were interpreted without any knowledge of the result of the operation. The question to be answered from inspection of the radiographs was: Would a bypass have been possible or not? The results of inspection of the angiograms are summarized in *Table VI.* In 81 per cent of cases it was possible to predict success or failure of the operation of EDFA purely on the basis of a good or bad run-off. A good popliteal artery and a healthy trifurcation were almost always associated with a good result. Poor filling of the trifurcation and especially poor filling of the tibial arteries at the level of the midcalf were usually followed by failure. In 19 per cent of cases we could not predict the result. In 6 cases bypass was not possible and yet EDFA achieved a successful result. In 5 cases a bypass would have been possible but failure resulted. One of these cases was successfully treated by femoropopliteal bypass. The other cases could not have been treated by the bigger operation because their general condition was so poor.

Initially we requested oblique view angiograms of the deep femoral artery to reveal atherosclerotic lesions not seen on the anteroposterior view. We no longer take these oblique exposures because the artery is to be exposed and in general angiography tends to reveal less disease than that found at operation. In any event the purpose of the operation is to widen the deep femoral trunk without removing the atheromatous lesion.

Discussion

Until recently there have only been three operations for claudication, rest pain and gangrene due to atherosclerotic disease below the level of the inguinal ligament: femoropopliteal bypass, lumbar sympathectomy and amputation. Now EDFA adds a fourth possibility for which the indications have yet to be clearly defined. What does seem clear is that an EDFA operation can in many cases produce as good a result as a femoropopliteal bypass. From this series it seems that the clinical indications for EDFA are severe claudication, rest pain and ischaemic ulceration of the leg. Gangrene may be helped but less often than had been hoped.

Poor results of EDFA seem likely where there is a poor run-off in the angiograms, especially where the tibial arteries are not visualized. As would be expected, diabetics fare badly, as well as patients with extensive digital gangrene (*Table II*). The more severe the distal artery obstruction the less likely is a proximal arterial reconstruction to achieve success. Whether lumbar sympathectomy in combination with EDFA may offset this difficulty remains to be seen.

The advantages of EDFA are that it is simple and relatively free of complications. A striking advantage over femoropopliteal bypass is that swelling of the leg does not occur following EDFA, whereas although after bypass it may not be permanent it certainly lasts a year or so in the majority of cases.

All the patients surveyed in this paper had crippling claudication often associated with rest pain. The unexpected improvement in the former symptom raises the question as to whether the EDFA should be extended to patients who complain of a less severe claudication.

The haemodynamic effect of widening the trunk of the deep femoral artery to produce such a dramatic change in the arterial blood flow to the lower limb, and the value of flow and pressure measurement in these cases are the subjects of two further papers (Berguer et al., 1975; Roberts et al., 1975). Suffice it to say that the principle is to increase the surface area in the branching system of an arterial tree. What is needed for more precise definition of the indications for EDFA are methods of measuring the run-in and the run-off. It is hoped that modern non-invasive methods of measuring arterial circulation may be of value in determining the potential of arterial reconstruction. It is well known that claudication distance can increase spontaneously and in many cases the symptoms may disappear. Perhaps the operation of extended deep femoral angioplasty stimulates the processes of spontaneous resolution by augmenting flow into the collateral circulation.

Lastly, what are the indications for femoropopliteal bypass? We now believe it to be limited to cases of digital gangrene where the run-off permits a bypass to be done or where an EDFA has failed to produce improvement.

Hydronephrosis complicating aortic reconstruction

GORDON HEARD AND GRAHAM HINDE*

SUMMARY

Prompted by an encounter with a symptomatic case, a study has been made of hydronephrosis complicating operations for aortic reconstruction.

Twenty patients operated upon consecutively for occlusive vascular disease and undergoing reconstructions involving the use of synthetic material in the vicinity of the ureter have been investigated by intravenous pyelography.

The incidence of hydronephrosis in pyelograms after a year or more was 10 per cent of the patients and 5·7 per cent of the ureters at risk. Dilatation, when it arose, was always apparent in the immediate postoperative period, but half of the dilatations evident at that time resolved within a year.

THERE have been few reports of hydronephrosis occurring in patients who have undergone abdominal arterial reconstruction. Lytton (1966) described 2 patients. In one a synthetic aorto-iliac bifurcation bypass had been complicated by the development of a left hydronephrosis, and in another there was bilateral ureteric obstruction which was more marked on the right. Thomford and Dorfman (1968) and Ehrlich et al. (1972) reported single cases in which the ureter lying between the prosthesis and iliac artery had become obstructed.

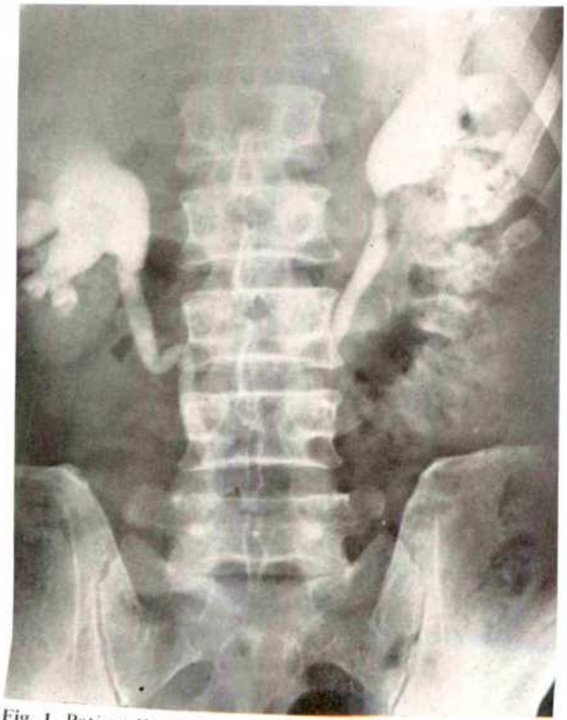

Fig. 1. Patient W. F. B. Intravenous pyelogram showing bilateral hydronephrosis.

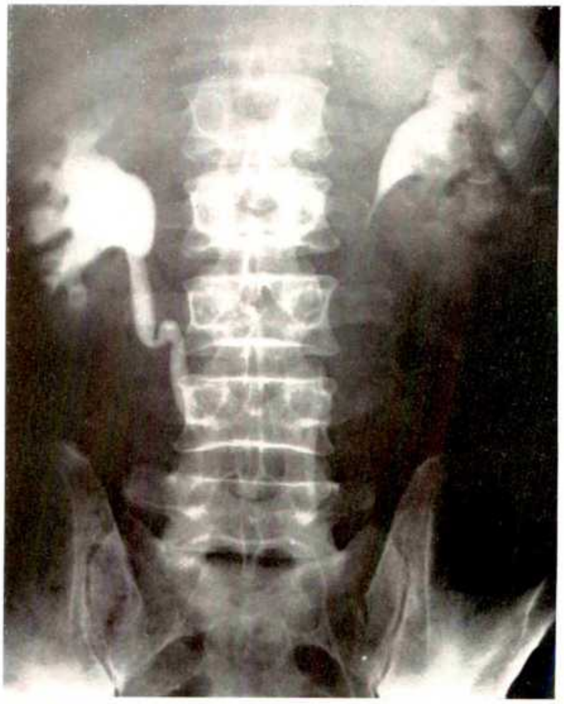

Fig. 2. Patient W. F. B. Intravenous pyelogram 1 month later showing resolution of the left hydronephrosis.

Case report

W. F. B., a male patient aged 49, presented with intermittent claudication due to bilateral aorto-iliac occlusion. Synthetic bypass of the lower aorta and common iliac arteries was carried out, with satisfactory restoration of pulses. The patient's postoperative course was uneventful but he returned at 2 months with frequency of micturition and loin pain. Intravenous pyelography showed bilateral hydronephrosi (*Fig.* 1). One month later the left renal tract had becom normal (*Fig.* 2). Further pyelograms showed slight improvemen on the right side, and at 18 months (*Fig.* 3) there was on slight residual fullness.

This being our first experience of the problem a finding no reported indication of its frequency clinical significance, the present study was embark upon.

A series of 20 patients undergoing aorto-iliac aortofemoral reconstruction involving the us synthetic tubes or patches in the vicinity of the u

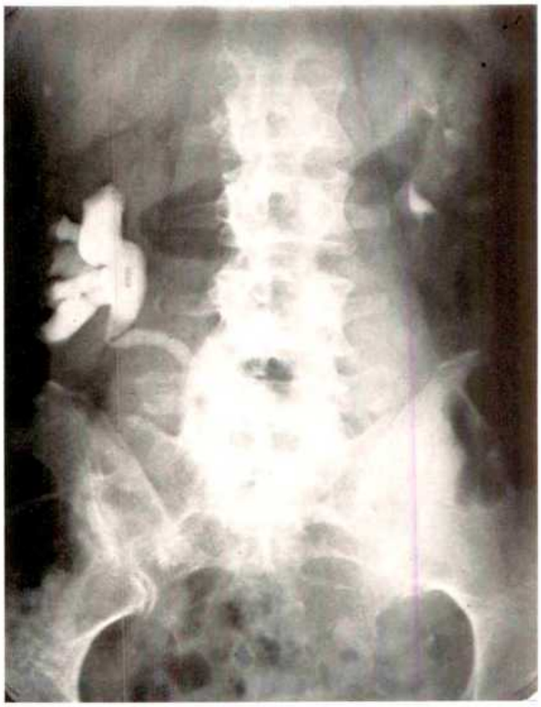

Fig. 4. Early postoperative intravenous pyelogram showing hydronephrosis on the right side.

and operated upon consecutively, has been investigated by intravenous pyelography. The indication in every case was occlusive arterial disease. No patient with aneurysm was included.

Findings

Preoperative pyelograms

These were carried out in 11 of the 20 patients. Only one was abnormal, displaying a slight fullness of the right renal pelvis of doubtful significance which remained unchanged in the late postoperative films.

Postoperative pyelograms

These were performed early (10–14 days) and late (after an interval of a year or more).

Early postoperative examinations were carried out in 13 of the 20 patients. There were 4 patients in whom hydronephrosis had developed, 3 on the right side (*Figs*. 4, 5, 6*a*) and 1 on the left (*Fig* 7*a*). Preoperative pyelograms had been undertaken and were normal in all 4 cases.

Late postoperative films were obtained in every patient. In 2 cases the earlier hydronephrosis had resolved (*Figs*. 6*b*, 7*b*), the other 2 persisting unchanged. In no patient did a hitherto undemonstrated hydronephrosis appear in the late pyelograms.

Type of operation performed

In 4 patients (with 7 ureters at risk) an aorta to external iliac synthetic bypass had been performed, and there were 2 instances of early hydronephrosis, 1 persisting (*Figs*. 4, 7).

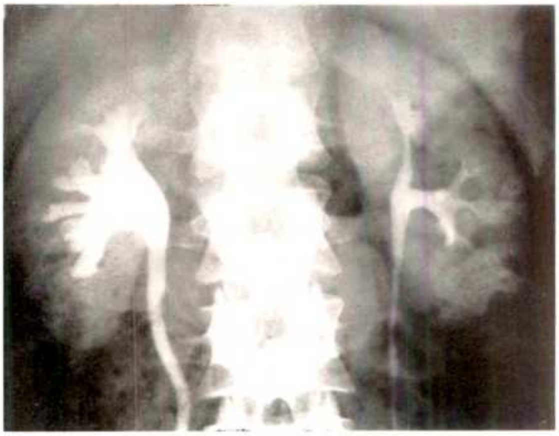

Fig. 5. Early postoperative intravenous pyelogram showing hydronephrosis on the right side.

In 12 patients (21 ureters at risk) an aortofemoral synthetic bypass had resulted in 1 early hydronephrosis persisting unchanged at 1 year (*Fig*. 5).

In 5 patients (7 ureters at risk) who had had a thrombo-endarterectomy and patching procedure of the aorta and common iliac artery, there was dilatation on the early pyelogram in 1 patient only and this resolved within the year (*Fig*. 6).

Relationship between ureter and reconstruction

Of 16 ureters left lying in front of the reconstruction, only 1 developed dilatation and this was transient. Of 13 ureters in which the position was not recorded, 2 showed a hydronephrosis, 1 being persistent at 1 year.

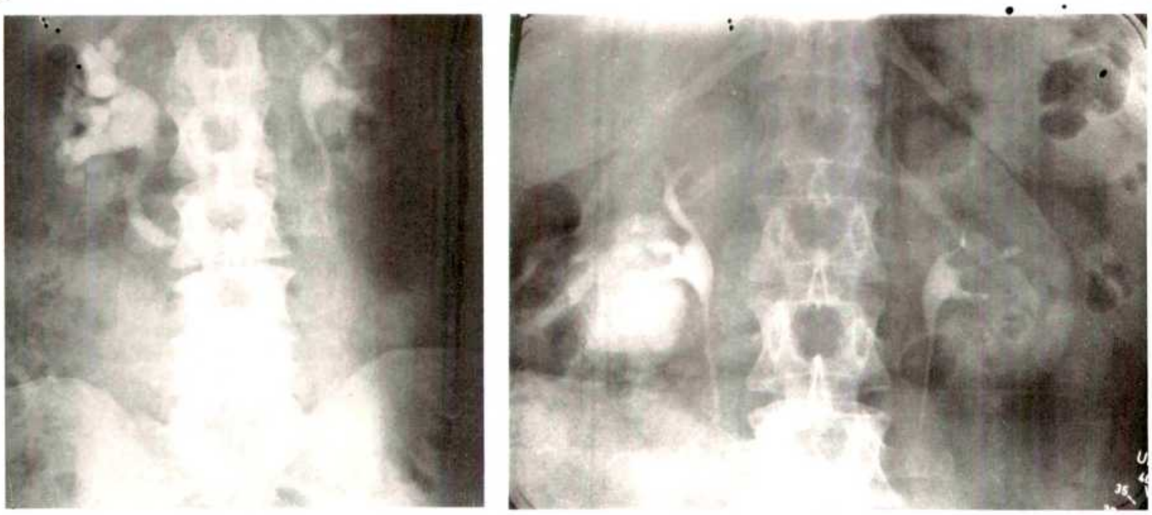

Fig. 6. *a*, Early postoperative intravenous pyelogram showing hydronephrosis on the right side. *b*, Late postoperative intravenous pyelogram showing resolution of the right hydronephrosis.

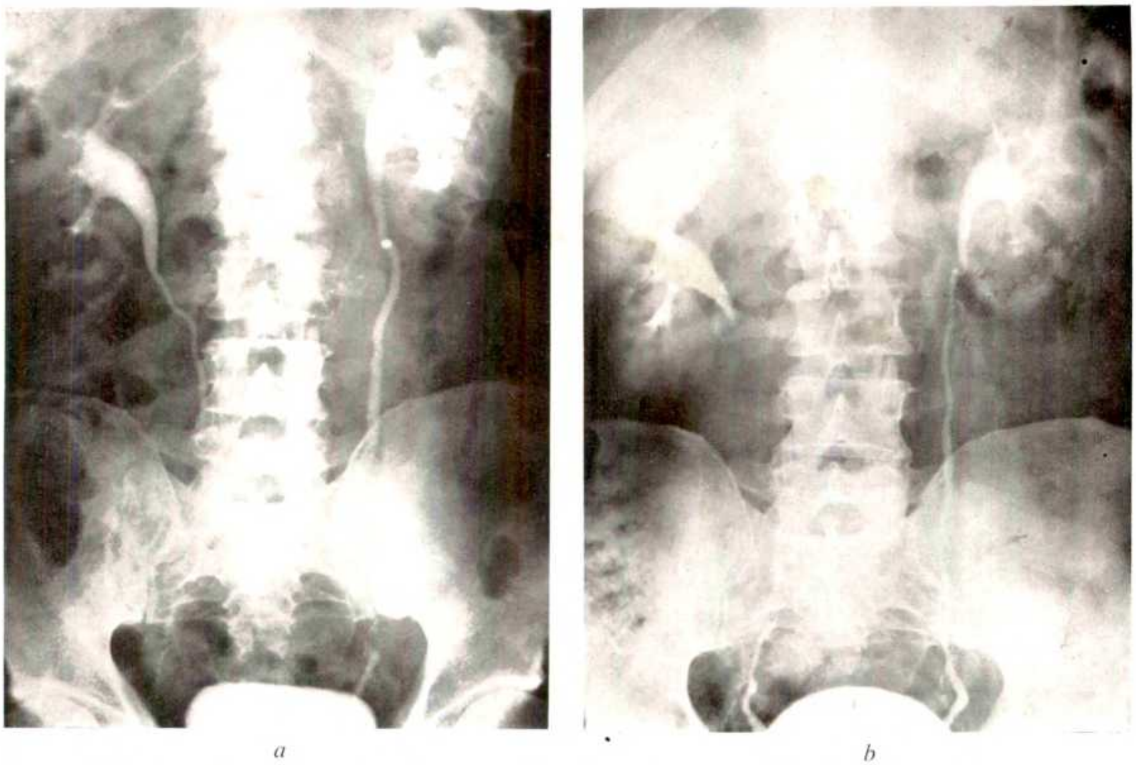

Fig. 7. *a*, Early postoperative intravenous pyelogram showing hydronephrosis on the left side. *b*, Late postoperative intravenous pyelogram showing resolution of the left hydronephrosis.

Of 6 ureters lying behind the prosthesis, 1 developed a hydronephrosis which was persistent in the late pyelogram.

Clinical features

None of the patients developing hydronephrosis had any symptoms which could be attributed to a urinary disorder.

Discussion

In 20 patients with 35 ureters at risk there was persistent dilatation in the late pyelograms in 2 patients, an incidence of 10 per cent of the patients or 5·7 per cent of the ureters at risk.

It would appear that if ureteric obstruction is going to arise it will do so in the early postoperative period. Neither patient with late hydronephrosis had a normal immediate postoperative pyelogram. This is also suggested by the findings in the patients reported by Lytton (1966) and by Thomford and Dorfman (1968) where pyelograms on the twelfth and sixteenth day showed the abnormality.

On the other hand, if obstruction is evident in the early postoperative films there is a good chance of later resolution. This was complete in 2 of the 4 instances. Complete resolution on one side and improvement on the other was also seen in the patient whose clinical presentation prompted this study.

The ureters may be involved in any form of reconstruction where foreign material is implanted, whether by a reconstruction behind the ureter or in a bypass behind or in front of the ureter. It is not possible from our observations to deny or confirm the suggestion made by Lytton (1966) and Thomford and Dorfman (1968) that the complication is more likely to arise if the ureter is left between the prosthesis and the iliac vessels.

It is presumed that the ureter becomes involved in the fibrous reaction around the prosthesis. Pulsatile compression may also play a part (Cockett et al., 1965).

There seems to be a higher risk where the distal vascular anastomosis is at iliac rather than femoral level (2 in 7 ureters at risk as against 1 in 21). This may be due to more extensive dissection of the ureter in such cases or to the ureter being caught in the angle between the graft and the vessel proximal to the anastomosis.

What measures may be taken to reduce the incidence of ureteric involvement in arterial reconstruction?

Although it cannot be regarded as of proved value, it would seem wise to place the ureter anterior to the graft when this can be done readily without excessive dissection and especially in the aorto-iliac bypass. When an aortofemoral procedure is being carried out blind digital dissection of the tunnels at the brim of the pelvis can leave the ureters either in front or behind, and more extensive exposure, particularly on the left side, may be necessary to be sure of the position of the ureter.

Fatty tissue, peritoneum or even omentum might be interposed between the ureter and the prosthesis, or the synthetic tube may be routed in such a way as to cross the ureter well above or below the pelvic brim. These alternatives deserve further study.

Detection of hydronephrosis following aortic reconstruction

All patients undergoing aorto-iliac and aortofemoral reconstruction should be subjected to pyelography in the early postoperative period. If the pyelogram is normal there is little likelihood of the later development of ureteric obstruction.

Management of established hydronephrosis

Where an early hydronephrosis is apparent a conservative attitude is justified, there being a 50 per cent chance of complete resolution within a year and a further chance of improvement.

In our 3 patients in whom hydronephrosis has persisted (i.e. 2 in the series and the case initially encountered) it has been mild in degree and not progressive. Active treatment has therefore not been indicated. The latter would, of course, be necessary in the event of progressive dilatation or impairment of renal function.

In Lytton's (1966) 2 cases and in the single cases of Thomford and Dorfman (1968) and Ehrlich et al. (1972) the ureter appeared to be compressed between the prosthesis in front and the iliac artery behind, and a ureterolysis with re-routing of the ureter anterior to the prosthesis was carried out in every case. However, while Lytton (1966) and Ehrlich et al. (1972) undertook and advocated re-routing by division and reanastomosis of the ureter, Thomford and Dorfman (1968) preferred to divide and reanastomose the prosthesis. The choice is not easy since, while division of the prosthesis carries the direct risk of vascular complications, division and anastomosis of the ureter might be followed by urinary leakage with some risk of infection of the adjacent synthetic prosthesis. There would also be the possibility of fibrous stricture at the site of the ureteric anastomosis.

Small doses of subcutaneous sodium heparin in the prevention of deep vein thrombosis after elective hip operations*

VENOUS THROMBOSIS CLINICAL STUDY GROUP†

SUMMARY

The efficacy of small perioperative doses of subcutaneous heparin in preventing deep vein thrombosis has been studied in a controlled clinical trial on 64 patients undergoing elective hip surgery. The results indicate that the regimen of sodium heparin used was safe provided that the correct dose is given. It reduced the frequency of postoperative deep vein thrombosis from 37 to 7 per cent.

THE incidence of deep vein thrombosis after operations on the hip is high (Field et al., 1972; Kakkar et al., 1972). Because it is known that quantities of heparin insufficient to alter the overt ability of the blood to clot (5000 units 12-hourly) reduce the incidence of deep vein thrombosis in general surgical, thoracic and gynaecological patients (Williams, 1971; Gordon-Smith et al., 1972; Kakkar et al., 1972; Nicolaides et al., 1972; Ballard et al., 1973; Gallus et al., 1973), this technique has also been applied to those having either emergency or elective hip operations, but apparently without effect (Kakkar et al., 1972). A slightly more frequent dose of heparin (5000 units 8-hourly) has been shown to halve the incidence of thrombosis (detected by the ^{125}I-fibrinogen test) in patients operated upon for fracture of the femoral neck (Gallus et al., 1973), but subsequent trials produced conflicting results (Hampson et al., 1974; Morris et al., 1974). This paper reports a study of an 8-hourly regimen in patients undergoing elective operations on the hip.

Patients and methods

Sixty-four patients who were to undergo elective hip operations (total hip replacement) were admitted to the trial and were allotted to either a control or treatment group by drawing envelopes. All received the hospital routine of supervised leg and breathing exercises before and after operation and were made to walk with crutches on the first postoperative day. In the treatment group sodium heparin (5000 units in 0·2 ml) was given subcutaneously 2 hours before operation and thereafter 8-hourly for 10 days by the method previously described (Griffith and Boggs, 1964; Nicolaides et al., 1972). The amount of blood transfused at operation and the quantity of the suction drainage from the wound in the first 24 hours were measured.

The diagnosis of deep vein thrombosis in the calf of the affected limb and distal to the inguinal ligament on the opposite side was made by the ^{125}I-fibrinogen test using a Pitman 235 isotope localization monitor (Kakkar et al., 1970). Patients were considered to have deep vein thrombosis when an increase of 20 was observed in the percentage value of radioactivity (in the calf of the operated limb and in the calf or thigh of the opposite limb) at the same place on two different days or between two adjacent sites, provided that this increase persisted for more than 24 hours. Patency of the deep veins between the popliteal and inferior vena cava was tested on the fifth and tenth days after operation with an ultrasound generator using the Doppler principle (Parks blood flow detector, Model 801). Changes in the blood velocity during quiet breathing, during a Valsalva manœuvre and on compressing the calf and thigh muscles were recorded. The veins were considered to be patent when the flow in the femoral vein in the groin was phasic with respiration, stopped at the height of Valsalva and increased in velocity with muscle compression while the long saphenous vein was occluded at the knee. Venography was done when the ^{125}I-fibrinogen test indicated deep vein thrombosis in the popliteal or more proximal veins, or on evidence of venous occlusion from ultrasound examination.

Table I: INCIDENCE OF DEEP VEIN THROMBOSIS

	No. of patients		
Group	Admitted	Excluded	DVT
Control	30	0	11
Test	34	4*	2

DVT, Deep vein thrombosis. Fisher's exact test, $P = 0{\cdot}0046$.

* A heparin injection was accidentally omitted in 3 patients and severe bleeding from heparin overdose occurred in 1 patient.

Results

Sixty-four patients were admitted to the trial; 4 were subsequently excluded for the following reasons. In 3 patients a dose of heparin was omitted. One patient had a severe haemorrhage on the third postoperative day as a result of a large dose of heparin given in error. Heparin was discontinued and the patient was excluded from the trial. None of these patients

Table II: DISTRIBUTION OF FACTORS PREDISPOSING TO DEEP VEIN THROMBOSIS AND THEIR RELATIVE RISKS

	Risk factors and their weights*				
	Carcinoma (0·19)	Obesity (0·38)	Previous DVT (0·69)	Varicose veins (0·60)	Sum of (weight × number of patients) of all risk factors
Number of patients in control group	0	10	4	4	8·96
Number of patients in test group	1	12	2	4	8·53
Difference between the two groups	−1	−2	+2	0	0·43†

DVT, Deep vein thrombosis.

* Weights are expressed as the natural logarithm of relative risk.

† The relative risk in the unmatched patients of the control group is given by the antilogarithm of 0·43 = 1·5, i.e. the increased risk in the control group is approximately equivalent to 1 patient.

Table III: AMOUNT OF BLOOD TRANSFUSED, POSTOPERATIVE BLOOD LOSS AND INCIDENCE OF WOUND HAEMATOMA

Group	Blood transfused* (mean no. of units ± s.d.)	Suction drainage* (mean no. of ml ± s.d.)	Wound haematoma (no. of patients)
Control	2·0 ± 0·69	333 ± 233	3
Test	2·4 ± 0·64	388 ± 104	4

* *t* test, $P > 0{\cdot}05$.

developed thrombosis as detected by the ^{125}I-fibrinogen test. Of the remaining 60 patients, 30 were in the control group and 30 in the heparin group. The frequency of deep vein thrombosis was 11 out of 30 (37 per cent) in the control group and 2 out of 30 (7 per cent) in the test group (*Table I*). This difference was highly significant (Fisher's exact test, $P = 0{\cdot}0046$). In the 2 patients in the test group who developed thrombosis the thrombus occurred in the operated leg and remained confined to the calf. In the control group all the thrombi were first detected in the calf. Thrombosis was bilateral in 4 patients, occurred in the operated leg only in 4 patients and in the opposite leg only in 3 patients. There were thus 15 limbs with thrombosis. In 3 (20 per cent) of these the thrombotic process extended proximally. This extension was into the popliteal vein in one, into the superficial femoral in one and into the iliofemoral segment in another patient. The last was detected with Doppler ultrasound. In these 3 patients the diagnosis was confirmed by venography and the patient was immediately confined to bed and treated with a continuous intravenous infusion of heparin (10 000 units 6-hourly for 48 hours) and oral anticoagulants. None of these or any other patients in this trial developed clinical evidence of pulmonary embolism.

The control and test groups were comparable for age (mean age and standard deviation: control group 64 ± 11·9; test group 63 ± 12·3), but not for weighted risk factors (cancer, obesity, previous deep vein thrombosis, varicose veins), as shown in *Table II*. The use of weights for risk factors calculated from previous data (Nicolaides et al., 1973) is subject to criticism that a different population may be under study, but they express relative risk and as such are independent of the incidence of thrombosis. If a correction is made for the increased risk in the control group the results will still be significant (Fisher's exact test: $P = 0{\cdot}0094$). The amount of blood transfused, postoperative blood loss and incidence of wound haematoma in the two groups were comparable (*Table III*).

Discussion

Low dose heparin probably works by enhancing the activity of antithrombin III (Damus et al., 1973; Wessler and Yin, 1973) in forming complexes with serine proteases such as activated factors X and XI, thus rendering them incapable of taking part in the coagulation cascade. If heparin is administered before these factors are activated by events which accompany local tissue trauma and the general effects of injury, then only small quantities are needed to prevent intravascular thrombosis and, as this study suggests, to reduce its tendency to extend. The plasma level of heparin produced by 5000 units given subcutaneously 2 hours before operation becomes too low to be detected within about 6 hours (Kakkar et al., 1972), even when the most sensitive method is used (Wessler et al., 1971). However, the blood transfusion requirements are increased in patients undergoing abdominal and thoracic operations when this dose of heparin is administered 8-hourly (Gallus et al., 1973), which suggests that clotting is less efficacious than normal. Thus, though it is theoretically desirable to administer heparin 5–6-hourly, a reasonable compromise between prophylaxis of deep vein thrombosis and the risk of bleeding is an 8-hourly regimen. Our evidence suggests that the increased tissue trauma and the increased immobility imposed on the patient undergoing hip operations necessitate such a regimen, in contrast to the patients subjected to operations on soft tissues (Williams, 1971; Gordon-Smith et al., 1972; Kakkar et al., 1972; Nicolaides et al., 1972; Ballard et al., 1973; Gallus et al., 1973).

We do not have evidence that morbidity is increased by the use of low dose heparin, but there is in this therapy the ever-present risk of overdose which did occur in one of our patients. If this preventive measure is to be widely adopted, a method such as the use of disposable cartridges containing the correct dose should be sought to eliminate human error. Further, it is a commentary on human frailty that in 3 patients the heparin was omitted even though we were carrying out a trial where supervision might have been expected to be adequate. It may well be that the universal or near universal use of heparin in this manner (or for that matter any other form of blanket prophylaxis such as preventive antibiosis for wound infection) will fail to achieve the theoretically maximum effect because it cannot be made free of human error. Concentration on the evaluation of risk and the selective use of prophylaxis in patients seriously in danger may ultimately prove a more attractive strategy. Certainly we would not wish our results to be construed at this stage as an argument for the widespread use of heparin in the prophylaxis of deep vein thrombosis in hip surgery.

This caveat is the more true in that two questions remain unanswered. First, does the use of low dose heparin affect the incidence of pulmonary embolism? The reduction in the incidence of thrombosis in the axial veins of the leg shown in this and other studies (Williams, 1971; Gordon-Smith et al., 1972; Kakkar et al., 1972; Nicolaides et al., 1972; Ballard et al., 1973; Gallus et al., 1973), and the results of earlier work on the incidence of pulmonary embolism by Sharnoff (Sharnoff and De Blasio, 1970) suggest that this should be so, but a larger investigation will be required to provide statistical confirmation. Secondly, what is the incidence and clinical pattern of deep vein thrombosis later in convalescence after hip surgery, for example in the second or third week? A venographic study suggests that half of all patients may have thrombi in leg veins at this time and that many of the thrombi are in the femoral and more proximal veins (Johnson, 1974). In a recent clinical trial a large number of thrombi developed in the second postoperative week after heparin therapy was discontinued (Hampson et al., 1974). Further trials are needed to test the wisdom of prophylaxis throughout the patient's stay in hospital.

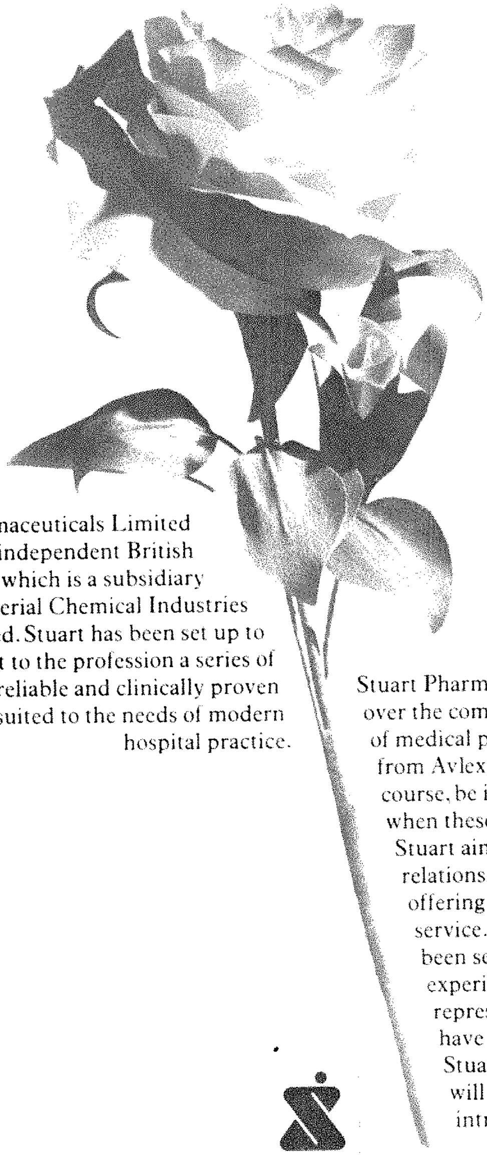
Stuart
blossoms

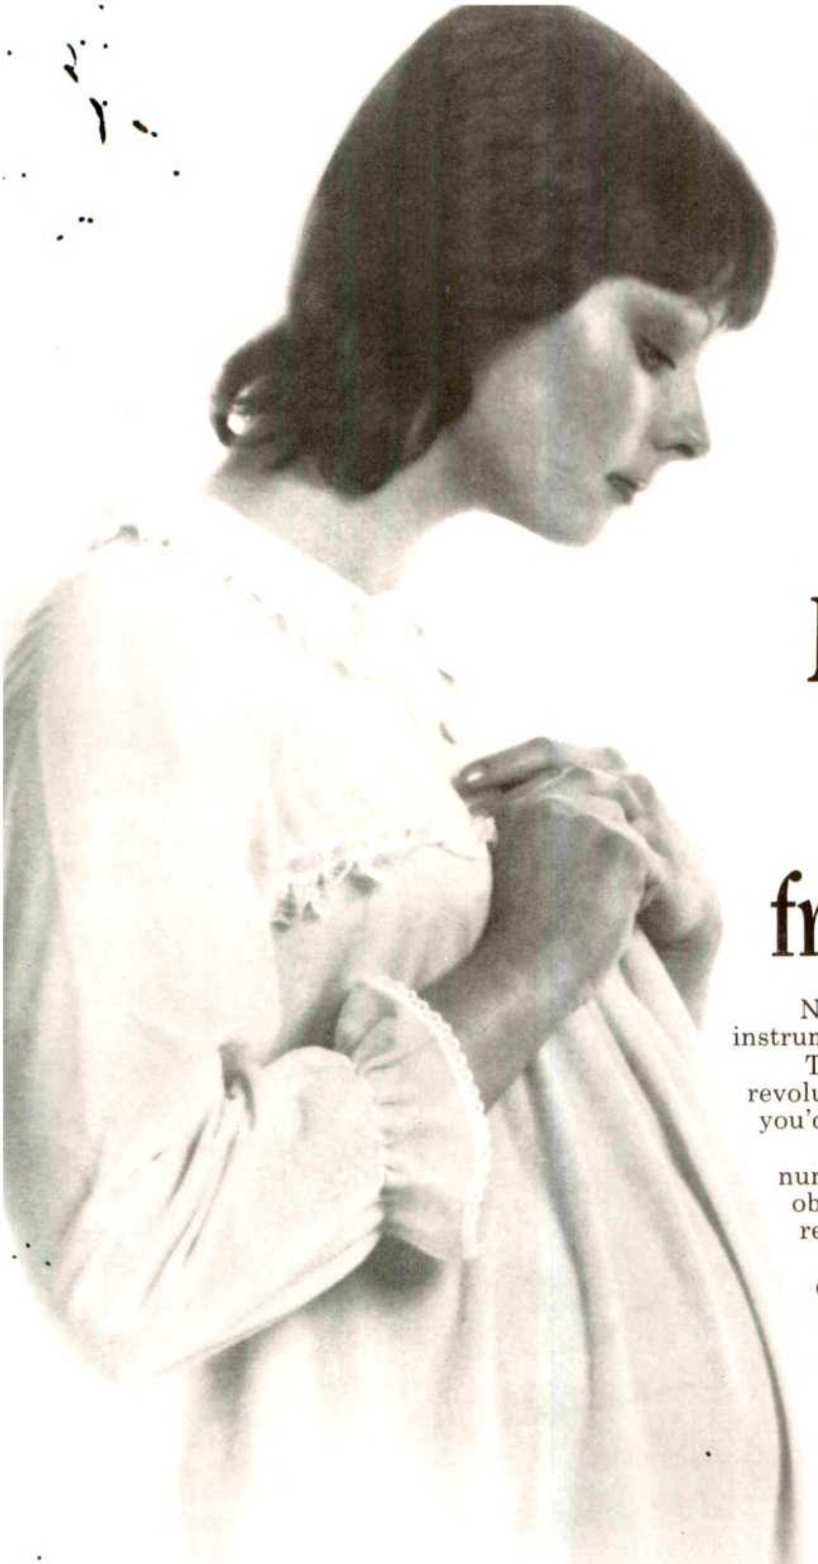


Stuart Pharmaceuticals Limited is a new, independent British Company which is a subsidiary Company of Imperial Chemical Industries Limited. Stuart has been set up to present to the profession a series of reliable and clinically proven products suited to the needs of modern hospital practice.

Stuart Pharmaceuticals will, over the coming year, market a variety of medical products currently available from Avlex Limited. You will, of course, be informed separately as and when these changes occur.

Stuart aims to develop a good working relationship with the profession by offering an efficient and courteous service. To ensure this all staff have been selected for their previous experience and before any Stuart representative calls on you he will have received extensive training in the Stuart range of products. Now if you will kindly turn over the page we will introduce the first of our products.

STUART



For Mother's Day...

from Seward.

Now there is a Seward range of instruments for gynaecology and obstetrics.

There's nothing particularly revolutionary about it. Yet it's everything you'd expect from Seward.

We worked closely with quite a number of leading gynaecologists and obstetricians and analysed their requirements down to the last detail.

That's why the new range is exceptionally comprehensive. Around 400 instruments altogether. All made in England—to the same exacting quality standards as all ou other instruments.

We carry ample stocks of our new gynaecology and obstetrics range. So we can supply whatever you need remarkably fast—normally within just a few days.

Now it could mean one less problem delivery for you to worry about.

seward–the fast word in quality

Quick Prep

Chlorhexidine Gluconate 0.5% w/v
in 70% Industrial Methylated Spirit.

The pick of the bunch for skin disinfection

'Dispray' 1 Quick Prep. (formerly known as Hibispray 1) is an ideal preparation for skin and hand disinfection in the busy hospital environment.

At the touch of a button it gives fast, easy and economical skin disinfection prior to surgery, injection or venepuncture.

When colour delineation is required eg. pre-operatively, 'Dispray' 3 is available with a red dye.

The 'Dispray' range combines effectiveness with convenience and economy.

Instant Availability.
No solutions to prepare.

Easy to use.
No swabs or bottles required.

Quick and Effective.
Rapid bactericidal action.

Efficient Application.
No wasted solutions.

Contents cannot be contaminated.
No rejected solutions.

Long Lasting.
Contents of one can treat 100sq. ft.

'Dispray' 1, 2, 3.

Your hands are your most important instruments-
it pays to take care of them

The obvious fact that a surgeon's hands are of prime importance to his work was borne in mind when 'Hibiscrub' was formulated. 'Hibiscrub' is designed to keep hands healthy, even after repeated use.

However, the prime importance of a handwash is effectiveness: rapid prolonged bactericidal action against skin bacteria is assured by the presence of the well-proven antiseptic 'Hibitane'.

"These studies have shown that a 4% chlorhexidine detergent solution ['Hibiscrub'] is a potentially outstanding addition to the small list of detergent-disinfectant preparations for the hands of surgeons and nurses, with a greater immediate effect than that obtained with the hexachlorophane or even the iodophor preparations."
British Medical Journal, (1973), 1, 510.

The construction of a skin-lined hemithorax in pigs

LADE WOSORNU*

SUMMARY

The feasibility of creating a skin-lined hemithorax was tested in 6 pigs. All the pigs survived intrapleural skin grafting, and within 3 weeks they doubled their mean initial weight from 16·0 ± 1·6 kg to 32·4 ± 2·6 kg. In 4 (out of 4) pigs the skin-lined cavity was opened successfully to the exterior; it had reproduced closely the contour of the hemithorax. It is concluded that it is feasible to construct a skin-lined hemithorax with a mean volume of 276·0 ± 19·6 ml in pigs, whose mean body weight was 37·5 ± 2·5 kg. This confirms earlier work in the rat.

It has been shown in short-lived experiments that it is feasible to implant prosthetic lungs (Bodell et al., 1965). Peirce (1966) suggested that if the pleural cavity were to house prosthetic organs permanently, it must first be exteriorized by lining it with silicone 'skin'. After showing that autogenous skin was more suitable as the new pleural lining, Wosornu (1972) described a reproducible technique for transforming the left hemithorax of Specific Pathogen Free rats into stable skin-lined cavities.

When it was found that the cavities could be opened to the exterior without embarrassing breathing in the contralateral lung, the experimental preparation was put forward as a model of a cavity which could be employed to house prosthetic organs inside the thorax.

The aim of the present experiments was to see whether it was feasible to use this technique to create similar cavities in a larger animal. A series of experiments identical in design to those described in the rat (Wosornu, 1972) were carried out on 6 pigs.

Materials and methods

Six pigs (4 male and 2 female) were employed. They were mixed Landrace strain of mean initial weight 16·0 ± 1·6 kg. They were kept under standard laboratory conditions in sties fitted with infrared lamps so that temperatures of 30 °C could be reached—an important consideration in the immediate postoperative period. They were fed once a day with 2 kg of concentrated pig food (Spillers, London), and the drinking water was replenished as required.

Under general anaesthesia autogenous skin bags were grafted into the pleural space. Anaesthesia was induced by halothane/air mixture using the technique described by Singh et al. (1971). The pigs were intubated and anaesthesia was maintained by positive pressure ventilation with the Palmer Ideal respirator.

Operative procedure

The shoulders and gluteal regions were prepared surgically for use as donor sites and split skin grafts were taken with a Humby knife. With 2/0 atraumatic silk, the sheets of skin were sutured together to form skin bags such that the hair-bearing surfaces were enclosed completely. A silicone tube 40 cm long (outer diameter 3 mm) was employed as an internal splint to give a roughly rectangular shape to the skin bag. The initial weight of the pigs and the size of the skin bags are given in *Table I.*

In the lateral position the left chest was opened through the bed of the unrestricted 5th rib. Bleeding was slight. The skin bag was laid inside the pleural space making sure that it reached the apex. The lungs were expanded and the chest was closed in layers without drainage. During the closure the lungs were inflated repeatedly. At the end of the operation 5 mega-units of crystalline penicillin were given by intramuscular injection, the chest wound and donor sites were sprayed with Nobecutane and the pig was returned to the warm sty. Intramuscular crystalline penicillin was repeated for the next 5 days (dose: 1 mega-unit once a day). Requiring hardly any supervision, the pigs resumed normal feeding the day after the operation.

Table I: WEIGHT OF PIGS AND SIZE OF SKIN BAGS

Pig no.	Initial body weight (kg)	Size of skin bag (mm)
1	21·3	125 × 125
2	18·2	163 × 75
3	18·2	180 × 85
4	12·7	138 × 113
5	10·9	138 × 76
6	14·3	125 × 75

Observations on the pigs with the skin-lined hemithorax closed

The pigs' general progress was observed and they were weighed once a week for 3 weeks; the skin-lined hemithorax was demonstrated radiologically; and the pressure inside the cavity was measured and compared with the normal pleural pressure.

Under radiographic control 20 ml of 45 per cent hypaque were injected into the skin-lined hemithorax on the tenth postoperative day in the first 3 pigs and chest X-ray films were taken. The procedure was repeated at the end of the third week in all 6 pigs. One of these pigs was then sacrificed for histological examination. On each occasion light general anaesthesia without intubation was employed. The pressure in the pleural cavities was measured in 5 pigs with a strain gauge manometer.

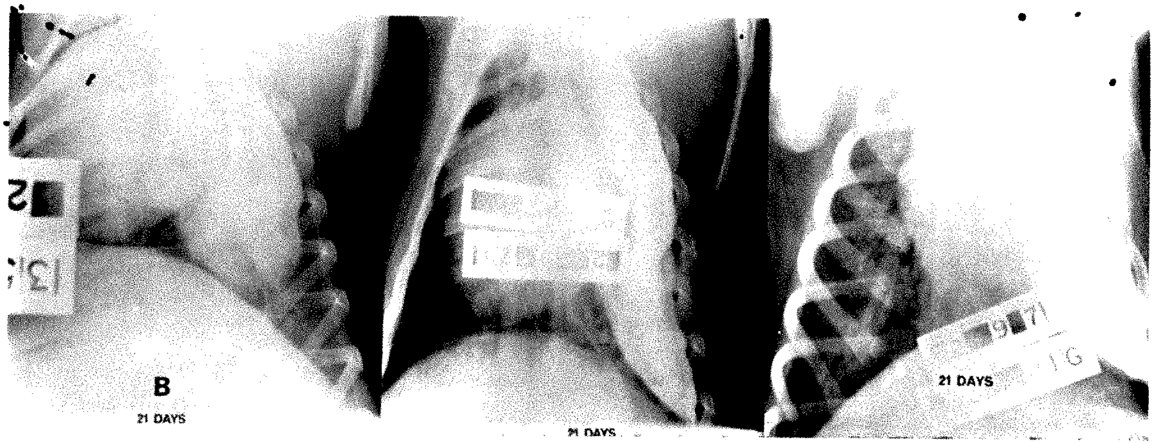

Fig. 1. Anteroposterior chest X-ray films taken in the third postoperative week (pig nos 1–3). The skin-lined hemithorax was outlined with 20 ml of 45 per cent hypaque. Fluid had accumulated in and had remained confined to the closed skin-lined cavity, the lung bases being clear on the X-ray films. The cavities had become nearly co-extensive with the hemithorax. The shape, however, varied from pig to pig. Mediastinal shift was moderate and the right lung fields were normal.

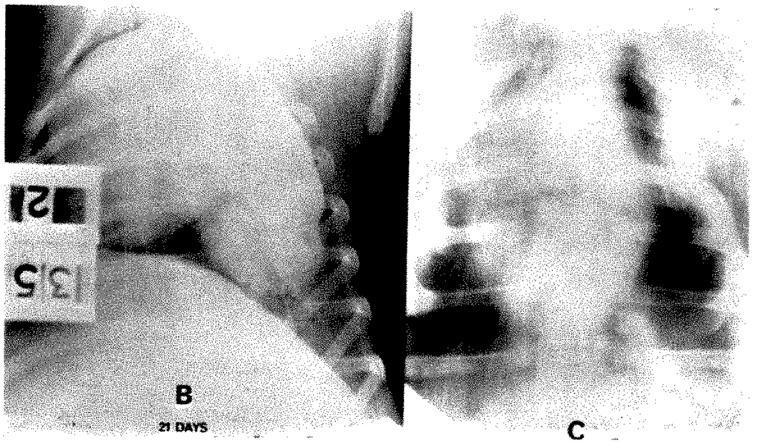

Fig. 2. Anteroposterior chest X-ray films of pig no. 3 before and after opening the skin-lined hemithorax to the exterior. *B*, The closed skin-lined hemithorax was outlined with 20 ml of hypaque at 3 weeks. *C*, Two weeks later the cavity was opened to the exterior. The intrapleural skin graft had closely reproduced the contours of the left hemithorax and the right lung field remained normal on both X-ray films.

Opening the skin-lined hemithorax to the exterior

The skin-lined hemithorax was opened to the exterior 5 weeks after intrapleural skin grafting. The pigs were anaesthetized and intubated as a precaution against protracted breath-holding. Pig no. 4 failed to survive intubation, which is sometimes a difficult technique because of the peculiar anatomy of the pig's larynx.

Anaesthesia was induced with halothane/air mixture and supplemented with intravenous pentobarbitone sodium (10 mg/kg). A disc of skin about 4 cm in diameter was excised from the 4th left intercostal space about 10 cm from the sternum. The intercostal muscles were excised to expose the thick, pearly white, skin-reinforced parietal pleura, a disc of which was excised; it measured about 15 mm in diameter. After the fluid in the skin-lined hemithorax was aspirated and its volume measured, chest X-ray films were taken.

Before and after opening the skin-lined hemithorax to the exterior, the following variables were measured: systemic blood pressure; electrocardiogram; arterial pH, $P\text{O}_2$ and $P\text{CO}_2$; and tidal air from the trachea and the skin-lined hemithorax. Details of these measurements will be described elsewhere.

Results

All 6 pigs survived the operation of intrapleural skin grafting. Their postoperative recovery was swift and uneventful. In the first 3 postoperative weeks the pigs doubled their mean initial weight from 16·0 ± 1·6 kg to 32·4 ± 2·6 kg. In 4 (out of 4) pigs the skin-lined hemithorax was successfully opened to the exterior. X-ray films of the skin lined hemithorax before and after thoracostomy are shown in *Figs.* 1 and 2. Paired data on pleural pressure were available for 5 pigs (*Table II*). *Table III* shows the volume of the skin-lined hemithorax 5 weeks after intrapleural skin grafting.

Table II: PLEURA PRESSURE IN (A) NORMAL PLEURA AND (B) CLOSED SKIN-LINED HEMITHORAX

	Pleural pressure (cm H_2O)					
	End of expiration		End of inspiration		Mean pressure	
Pig no.	A	B	A	B	A	B
2	5·0	8·0	−12·0	−10·0	−4·0	1·0
3	1·0	7·0	−15·0	− 7·0	−4·5	1·0
4	2·0	8·0	−10·5	− 8·0	−4·0	0·5
5	3·0	6·0	−10·0	− 4·0	−5·5	2·0
6	−2·0	4·0	−10·0	− 4·0	−6·0	2·0
Mean	1·8	6·6	−11·5	− 6·6	−4·8	1·3
s.e.m.	1·16	0·75	0·94	1·17	0·4	0·3
t	6·53		4·28		8·76	
P (d.f. = 4)	0·003*		0·013*		0·0009*	

* Significant.

Table III: WEIGHT OF PIGS AND VOLUME OF SKIN-LINED HEMITHORAX 5 WEEKS AFTER INTRAPLEURAL SKIN GRAFTING

Pig no.	Weight (kg)	Volume (ml)
2	36·8	255
3	41·4	230
4	40·1	340
5	28·2	255
6	40·9	300
Mean	37·48	276
s.e.m.	2·45	19·58

The implanted skin capsules 'took' on the surrounding intrathoracic structures, reproducing closely the outline of the hemithorax (*Fig.* 2). The average mean pressure in the closed skin-lined hemithorax was 1·3 ± 0·3 cm H_2O, compared with the average mean pressure of −4·8 ± 0·4 cm H_2O in the normal hemithorax ($P < 0·001$).

In 5 pigs of mean body weight 37·5 ± 2·5 kg, the mean volume of the skin-lined hemithorax was 276·0 ± 19·6 ml. This compared with a mean volume of 7·4 ± 0·3 ml in 15 rats of mean body weight 298·3 ± 9·0 g in an earlier series (Wosornu, 1971).

Conclusion

It was concluded that a technique which allowed the construction of a skin-lined hemithorax in rats is appropriate to a larger animal, the pig. Cavities with a volume of approximately 300 ml could be achieved in pigs with a mean weight of 37·5 kg. Such cavities compare with those in rats of mean weight of 298·3 g when average volumes of 7·4 ml were achieved.

Postvagotomy dysphagia

J. D. SPENCER*

SUMMARY

Following truncal vagotomy some patients develop dysphagia, which rarely can progress to complete obstruction. It has been postulated that haematoma formation in the tissues surrounding the lower oesophagus may lead to peri-oesophageal fibrosis and compression of the lumen of the oesophagus. This has been confirmed by open operation in only a few patients. A case is described in which oesophageal obstruction occurred 3 weeks after a vagotomy and pyloroplasty had been performed.

Case report

The patient was a 39-year-old West Indian male whose 8-year history of peptic ulcer symptoms had not been fully controlled by medical measures. In February 1974 a barium meal examination showed active ulceration in an already scarred duodenal cap. A chest X-ray was normal.

On 24 February 1974 he underwent a truncal vagotomy and Finney type pyloroplasty through an upper midline abdominal incision. The vagus trunks were divided and haemostasis achieved without injury to the oesophageal muscle. He made an uneventful recovery.

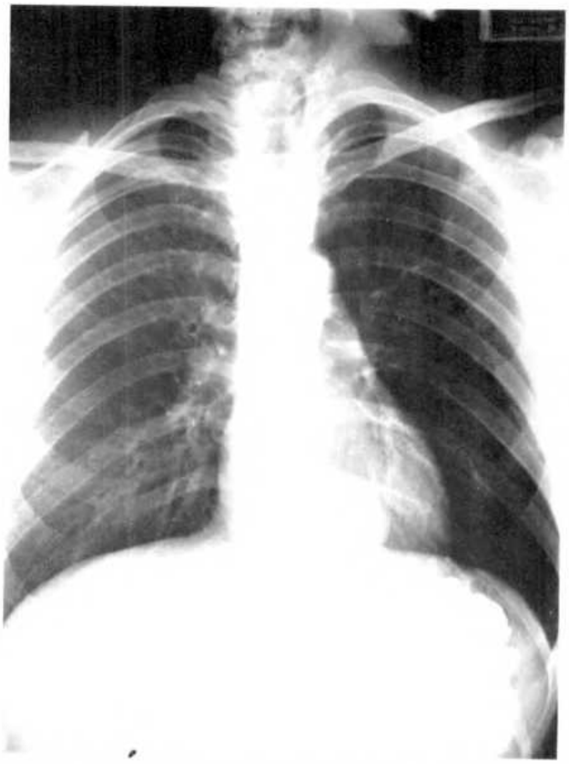

Fig. 1. Chest X-ray showing a smooth well-defined shadow lying medially at the left base.

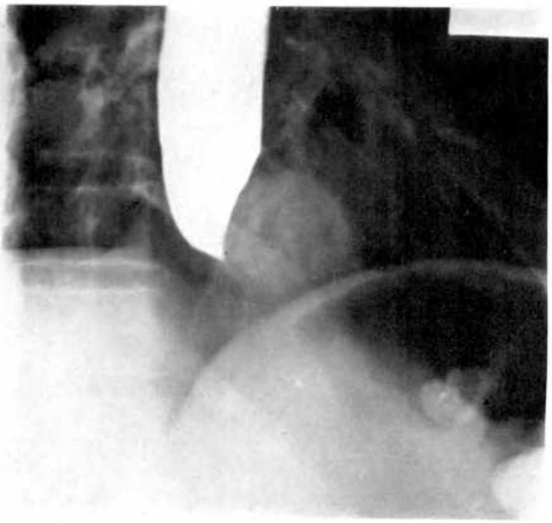

Fig. 2. Barium meal film showing the mass compressing the oesophagus at its lowest points.

On 14 March 1974 the patient was readmitted complaining of vomiting half an hour after meals. He indicated that food and fluid were sticking retrosternally. A chest X-ray (*Fig.* 1) revealed a shadow, smooth and well defined, lying medially at the left base. A barium swallow film (*Fig.* 2) showed that this mass was compressing the oesophagus at its lowest point. There was delay in the passage of barium through the obstruction, and the proximal oesophagus was dilated.

Initially treatment was conservative, the patient being fed intravenously. He underwent oesophagoscopy, and dilators passed to 27 F with ease on two separate occasions. Each time the mucosa was normal, but the relief obtained from bouginage proved to be temporary.

Seven weeks after his vagotomy and pyloroplasty another oesophagoscopy revealed complete obstruction of the lower oesophagus. The patient therefore underwent laparotomy through the previous upper midline abdominal incision. At the diaphragmatic hiatus the oesophagus, which otherwise was normal, was compressed by a mass of hard fibrous tissue. This mass completely surrounded, but appeared to be separate from, the oesophagus. A biopsy was taken, and the mass was dilated forcefully with the fingers to allow the oesophagus to re-expand. Biopsy of this material showed fibrous tissue with a few normal blood vessels. No evidence of starch granulomas was seen.

Recovery from this second operation was rapid and the patient left hospital after 8 days. When last seen 4 months after re-exploration the patient was symptom-free, and the radiological abnormalities could no longer be seen.

Discussion

The reported incidence of postvagotomy dysphagia differs widely, depending on the severity of the symptoms recorded. In a series of 1000 cases Wirthlin

---

* The Greenwich District Hospital and Miller General Wing, London.

and Malt (1972) found an incidence of dysphagia of 1 per cent after vagotomy. Williams and Cox (1969) cited a figure of 18 per cent in their series. Grimson et al. (1947) found that 33 per cent of patients complained of dysphagia if a transthoracic approach had been used for the vagotomy. It was noted by Dagradi et al. (1962) that a higher incidence of dysphagia could be found in the hands of certain surgeons who made a practice of searching for vagal nerve fibres in the oesophageal muscle.

Initially the cause of postvagotomy dysphagia was thought to be due to denervation of the sphincter mechanism of the lower oesophagus, and also to loss of normal peristalsis leading to a form of achalasia (Moses, 1947; Harris and Miller, 1960). Edwards (1970) showed by manometric and radiological studies of the oesophagus in patients with some dysphagia after vagotomy that the sphincter was intact and that peristalsis occurred normally. Carveth et al. (1962) attempted to denervate the lower oesophagus in dogs, and found that this could only be achieved by vagal nerve section at the level of the hila of the lungs.

Three cases have been described in the literature in which open operation has had to be carried out for complete obstruction of the lower oesophagus, some time after the original vagotomy. Bruce (1959) operated on a man with postvagotomy dysphagia. His symptoms started, as is often the case, 3 weeks after operation. After another 2 weeks he had developed complete obstruction, and was therefore fed by a jejunostomy. Oesophagoscopy revealed a normal oesophageal mucosa, but repeated bouginage failed to relieve the symptoms. The patient subsequently underwent a left thoracotomy, dense scar tissue being found to have surrounded the lower end of the oesophagus. This mass was adherent to the aorta, pre-vertebral fascia and the right lung. The lower oesophagus and this mass of scar tissue were excised and an oesophagogastric anastomosis carried out. Histology revealed a small but definite gap between the normal oesophagus and the fibrous tissue mass.

Guillory and Claggett (1967) described the finding of a dense ring of scar tissue surrounding the lower oesophagus in a case of postvagotomy dysphagia. This was partly excised and a modified Heller's procedure carried out. A left thoracotomy was the approach used in this case also. The third case was reported by Postlethwait et al. (1969) and was found to have a mass of fibrous tissue compressing the lower oesophagus. This mass of tissue was excised, using a left chest approach. The complete oesophageal obstruction was relieved in these 3 cases.

Comment

Postvagotomy dysphagia may appear some weeks after a seemingly successful truncal vagotomy. Usually the symptoms disappear spontaneously, and only occasionally is it necessary to resort to oesophagoscopy and dilatation. In just a few cases has a second operation been performed for oesophageal obstruction which had become complete.

From the evidence presented it would seem probable that the initial event in the production of postvagotomy dysphagia is haematoma formation around the lower end of the oesophagus. This eventually leads to peri-oesophageal fibrosis, causing compression of the lower oesophagus and very rarely complete obstruction.

The case we have described was one of the very few which did not respond to conservative measures, and it is of some interest that the mass causing oesophageal compression could be clearly seen on X-ray. The patient was not subjected to thoracotomy but to a lesser procedure, carried out through his original upper midline abdominal incision. This may have contributed to his rapid recovery, as may the fact that no direct attempt was made to dissect out the fibrous tissue mass which was compressing the lower end of the oesophagus.

Acknowledgement

I would like to thank Mr J. Candy for permission to publish details of this patient who was under his care.

The relationship of anaemia to gastric secretion more than 15 years after vagotomy and gastro-enterostomy

E. J. WHELDON, C. W. VENABLES AND IVAN D. A. JOHNSTON*

SUMMARY

Iron deficiency anaemia is common following vagotomy and gastro-enterostomy, and this study has shown that all the anaemic patients had low gastric secretion.

After correction of their anaemia, gastric secretion was increased, but was still very low, and when these levels were compared with secretion in fit non-anaemic patients it was found that the latter group had a significantly higher secretion, and that a high proportion of them showed evidence of incomplete vagotomy.

These results suggest that there is a relationship between the levels of gastric secretion in patients after vagotomy and gastro-enterostomy and the development of anaemia. It may be that inadequate gastric secretion impairs the release of elemental iron from the diet and its subsequent absorption.

PARTIAL gastrectomy, whether Polya or Billroth I, is known to be associated with a high incidence of anaemia developing a number of years after operation. This anaemia has been shown to be mainly due to iron deficiency (Hobbs, 1961). The incidence of anaemia varies widely (from 10 to 80 per cent) in different series, and Deller et al. (1962) calculated an average of 28 per cent from 33 reports. Macrocytic anaemia was reported by these workers in only 1·5 per cent of patients, but Jones et al. (1962) reported an incidence of 16 per cent. A study carried out by Mollin and Hines in 1964 found serum vitamin B_{12} and folic acid deficiencies in more than 25 per cent of their patients.

There has been a great deal of investigation into the possible causes of the iron deficiency anaemia following partial gastrectomy. Little evidence has been produced to indicate that these patients take an inadequate amount of iron in their diets. It would seem possible, therefore, that the anaemia might be caused by impaired absorption. It has been suggested by Stevens et al. (1959) that patients after partial gastrectomy are unable to increase dietary iron absorption in the presence of iron deficiency anaemia, whereas iron deficient patients who have not had gastric surgery are able to do so. Other workers have shown that absorption of both ferrous and ferric salts in anaemic patients after gastrectomy is as good as in anaemic patients who have not undergone surgery (Baird and Wilson, 1959). It would appear that postgastrectomy patients might have a limited ability to break down the protein complex of dietary iron, and it has been suggested that gastric secretion facilitates this breakdown (Goldberg et al., 1963; Jacobs et al., 1966).

All this work was carried out on patients following partial gastrectomy, and it was felt that loss of the gastric reservoir and glandular tissue might be responsible for the development of nutritional disturbances. It was hoped that with vagotomy and drainage these problems would not arise. Unfortunately, several workers have shown that a similar incidence of anaemia occurs following this operation (Burge and Pick, 1958; Cox et al., 1964).

A recent study of 230 patients who had undergone vagotomy and gastro-enterostomy more than 15 years previously (Wheldon et al., 1970) showed that this operation was associated with a high incidence of iron deficiency anaemia (30 per cent). There was no evidence of macrocytosis in any of the patients, and serum vitamin B_{12} levels were all within the normal range. When these patients were reviewed at 10 years after surgery (Feggetter and Pringle, 1963), the incidence of iron deficiency anaemia was 10 per cent. Anaemia after vagotomy and drainage develops later and is less severe than that recorded after gastrectomy (Jones et al., 1962).

It would appear that alteration in gastric secretion might play an important role in the development of iron deficiency anaemia, and a study was designed to investigate this.

Table I: DETAILS OF THE TWO GROUPS IN THE PRESENT STUDY

	Anaemic group ($n = 12$)	Non-anaemic group ($n = 11$)
Age (yr)	55·8± 8·4	55·6±5·9
Weight (kg)	60·2±10·3	68·5±6·2
Haemoglobin (g/100 ml)	8·5± 1·1	14·6±0·6
Time since vagotomy (yr)	17·1± 1·6	17·5±1·7
Length of history before vagotomy (yr)	8·2± 6·5	6·8±3·0

All results given as mean ±s.d.

Patients and methods

Twenty-three patients were investigated (*Table I*). Twelve had haemoglobin levels below 10 g/100 ml (70 per cent) at the time of their review and their mean level was 8·4 g/100 ml (58·9 per cent). There was no obvious cause of anaemia in these patients, e.g. haemorrhoids, positive occult blood or any obvious disease associated with anaemia. A dietician calculated the mean daily iron intake of each patient,

---

* Department of Surgery, University of Newcastle upon Tyne, Royal Victoria Infirmary, Newcastle upon Tyne.

and all the patients took more than the minimum daily requirement of 10 mg, the mean being 16·1 mg.

The remaining 11 patients were selected because at the time of their review they were completely well and had normal haemoglobin levels (mean value 14·6 g/100 ml). The two groups were comparable for age, length of history before operation and length of follow-up.

There was a difference in the mean weights of the two groups: 68·5 kg in the non-anaemic patients and 60·2 kg in the anaemic patients. This was partly explained by the fact that there were 2 women in the anaemic group, and there were no women of comparable status in the non-anaemic group. The actual weights of the patients in this study were compared with their standard weights calculated from their age, sex and height (Kemsley et al., 1962). There was no significant difference between their actual and standard weights in the two groups. There was no alteration in the weights of the anaemic patients after correction of their anaemia. Haemoglobin was estimated by the cyanmethaemoglobin method, and serum iron by AutoAnalyzer.

The acid and pepsin secretory response to pentagastrin (6·0 µg/kg i.m.) and to insulin (0·2 u./kg i.v.) was assessed in all the patients either by separate tests or by a combined pentagastrin/insulin test (Venables, 1972). Gastric secretion was collected by a 'washout' technique in all but one patient; this technique allowed an estimate of uncollected secretion to be made. Acid was measured as total titratable acidity to pH 7·0 using an automatic titrimeter (Radiometer), and pepsin was measured as total peptic activity at pH 2·1 using a modification of Hunt's (1948) technique with albumin (Fr. V) as substrate and expressing results as equivalent to the peptic activity produced by a known amount of crystalline pepsin (Sigma 1 : 60 000). The outputs of acid and pepsin were calculated for the hour after pentagastrin stimulation and the peak 30-minute output after insulin.

As it could be argued that any secretory changes found were due to the presence of anaemia (Stone, 1968), the anaemia was corrected by the administration of oral ferrous gluconate 200 mg three times daily. At the end of 3 months' treatment the mean haemoglobin had risen from 58·9 to 95·3 per cent, and the serum iron from 31·5 µg/100 ml to 96·8 µg/100 ml. Repeat pentagastrin tests were carried out at this time.

Results

Estimation of acid and pepsin secretion before correction of the anaemia (*Fig.* 1) revealed that only 2 patients had acid outputs of more than 1 mEq/h and the mean output was only 0·6 mEq/h. Pepsin output was also markedly reduced, as 3 patients had no measurable pepsin response and the highest output was only 23·4 mg/h with a mean of 8·2 mg/h.

Three months later, after correction of the anaemia, there was a significant increase in the gastric secretion ($P<0{\cdot}01$). All but 2 patients had an increase in both acid and pepsin output. Six patients now had acid outputs of more than 1 mEq/h, but the mean response was still low at only 1·55 mEq/h. Pepsin output showed a threefold rise from a mean of 8·2 to 27·3 mg/h.

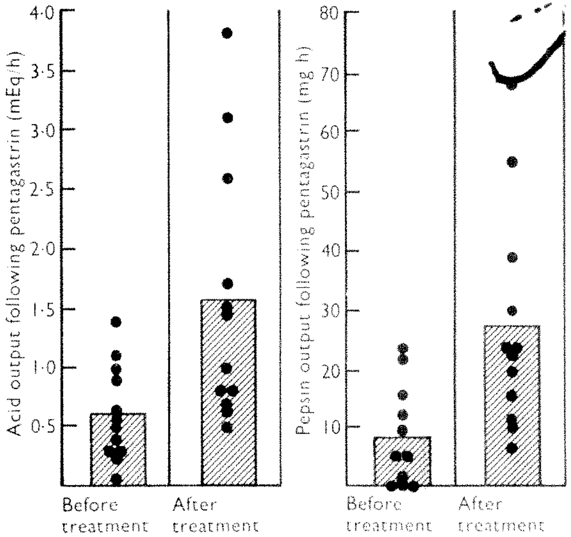

Fig. 1. Effects of correction of anaemia on gastric secretion. Acid output, $P<0{\cdot}01$ (u. = 25·5). Pepsin output, $P<0{\cdot}001$ (u. = 18·5).

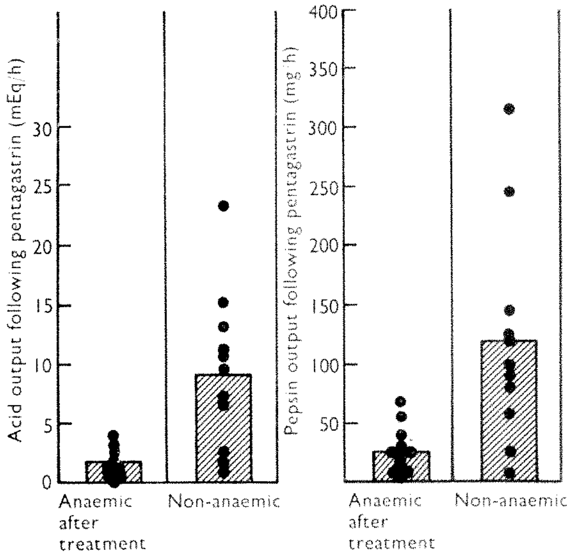

Fig. 2. Comparison of the gastric secretion of anaemic and non-anaemic patients. Acid output, $P<0{\cdot}001$ (u. = 9·5). Pepsin output, $P<0{\cdot}001$ (u. = 14).

The results obtained after correction of the anaemia were compared with those obtained in our non-anaemic group (*Fig.* 2). Only 3 of the non-anaemic patients showed acid outputs similar to those of the anaemic group and one of these had not had a 'washout' pentagastrin test so that the secretory response was probably an underestimate. The mean acid output in the non-anaemic group was 9·2 mEq/h and the pepsin output was 119·3 mg/h. These differences are highly significant ($P<0{\cdot}001$).

Table II: ASSESSMENT OF COMPLETENESS OF VAGOTOMY IN THE NON-ANAEMIC PATIENTS

Test	No. of patients
Hollander	
>20 mEq/l (positive)	9
<20 mEq/l (negative)	2
Insulin: pentagastrin acid ratio	
>45%	4
<45%	7

An attempt was made to assess the completeness of vagotomy in all the patients studied. This was done in two ways: either by the rise in acid concentration of more than 20 mEq/l after insulin stimulation (Hollander, 1946) or by an acid ratio of more than 45 per cent, calculated from the acid output response to insulin and pentagastrin (Venables, 1972). In the anaemic patients it was difficult to assess the completeness of vagotomy by either technique, as the acid outputs were so low. It was not possible, therefore, to say with certainty whether this low response was due to complete vagal section or to loss of secretory cells. Of the non-anaemic group (*Table II*), 9 showed a rise in acid concentration of more than 20 mEq/l, thus fulfilling Hollander's criteria for incomplete vagotomy, and 4 of these had acid ratios of more than 45 per cent, suggesting that the vagotomy was definitely incomplete.

Discussion

In our earlier study of patients who had undergone vagotomy and gastro-enterostomy more than 15 years previously (Wheldon et al., 1970) it was shown that iron deficiency anaemia was almost as common as that reported after gastrectomy. This was disappointing as it had been hoped that preservation of the gastric reservoir function of the stomach would prevent this complication.

One possible cause for this anaemia was a reduced iron intake, but dietary analysis failed to demonstrate this, supporting the findings of others (Pulvertaft and Cox, 1969).

Another mechanism could have been the bypassing of the duodenum in these patients, as Wallenstein (1958) suggested that this would reduce absorption from the duodenum and proximal jejunum. However, all our anaemic patients responded rapidly to oral ferrous gluconate, suggesting that this was not true for elemental iron.

Jacobs et al. (1966) have demonstrated that gastric secretion facilitates iron absorption. As dietary iron is not normally in its elemental form but bound to protein as an iron–protein complex, it is possible that the anaemia could be related to an inability to split this complex due to an effect of the operation upon gastric secretion. The present study was designed to investigate this possibility.

Because it might be argued that any secretory changes we found in our anaemic patients were due to the anaemia and not the cause of it, we repeated our secretory tests following correction of the iron deficiency and were able to confirm the findings of Stone (1968) that secretion of both acid and pepsin rose significantly after correction of the anaemia. However, even this increased secretory response was far lower than that found in our non-anaemic group.

Goldberg et al. (1963) suggested that 'acid' alone facilitated iron absorption, but Hines et al. (1967) felt that pepsin secretion was more important as this was capable of splitting the food iron–protein complex when activated by a fall in pH. Koepke and Stewart (1964) suggested that there was a factor present in gastric juice, similar to intrinsic factor, that enhanced iron absorption.

Whichever of the above possibilities is correct, it is likely that vagotomy will alter their roles as it results in a reduction of *all* gastric juice constituents.

Another possible cause for the reduction in gastric secretion found in our anaemic patients has been suggested by Williams (1964). He has postulated that the duodenal and bile juice reflux associated with a gastro-enterostomy may result in chronic gastritis, glandular atrophy and subsequent hyposecretion. Such a suggestion would explain why anaemia is less common after pyloroplasty where reflux is less (Wastell, 1969). It is of interest to note how many of our non-anaemic group had evidence of residual vagal function on insulin testing. This capacity to secrete acid may have protected the stomach from the effects of the reflux of alkaline secretion, and this in turn may have prevented mucosal atrophy.

Finally, it could be suggested that the increased rate of gastric emptying found after vagotomy and drainage (Owren, 1953; McKelvey, 1970) prevented the adequate mixing of gastric juice and food, reducing the liberation of elemental iron from the food while it was in contact with the iron-absorbing area of the small intestine. Incomplete vagotomy, even though it maintains a higher level of gastric secretion, cannot be the only factor, as several non-anaemic patients had no evidence of residual vagal function after insulin stimulation.

Acknowledgements

We wish to thank Professor A. L. Latner and the Department of Clinical Biochemistry, University of Newcastle upon Tyne, for their assistance with this study, Staff Nurse M. Curd for performing many of the secretory studies, Mrs M. Foster for her secretarial assistance and the members of the Department of Surgery for their assistance throughout the study.

Pancreatic pseudocysts in children: 4 cases from Uganda

J. WILSON CARSWELL, J. COTTER AND S. P. MASTER*

SUMMARY

Four cases of pancreatic pseudocyst in African children are described. There is some evidence that they followed pancreatitis of unknown aetiology. None had a history of trauma. Three were treated by cystogastrostomy, and the fourth by excision of the cyst.

PSEUDOCYSTS of the pancreas are not commonly seen in children (Mustard et al., 1969). Up until 1968 about 50 cases in children had been described in the literature. Sixty per cent of the cases are said to follow blunt abdominal trauma, 29 per cent to follow pancreatitis and 11 per cent to form a miscellaneous group, following such diseases as mumps and gallstones (Mustard et al., 1969). Typically the child presents with upper abdominal pain, nausea, vomiting, anorexia and weight loss. There may be a history suggestive of trauma or pancreatitis within the preceding 3 months. An epigastric mass is present although initially it may be masked by ascites. This mass is usually a tender unilocular cyst containing a litre or so of fluid. The pseudocyst displaces the adjacent organs, and this can be confirmed by X-ray examination. The serum amylase level is usually raised.

Untreated cysts may bleed, become infected or rupture, causing peritonitis. It will rarely disappear spontaneously. For these reasons surgery is usually recommended. In recent years cystogastrostomy and excision of the cyst have been the most commonly used procedures.

Four pancreatic pseudocysts seen in children in Kampala, Uganda, are described.

Case reports

Case 1: A 2-year-old Muganda boy, weighing 9·5 kg on admission, had been unwell for some months and had not been gaining weight. For 3 months his abdomen had been gradually distending, and in the month before admission his feet had started to swell. There was no history of abdominal trauma.

On admission he was wasted and anaemic and in a poor state of nutrition. There was gross abdominal distension, with ascites and prominent veins on the anterior abdominal wall. There was oedema of both feet. His skin was pale and his hair brown and brittle. For these reasons a clinical diagnosis of kwashiorkor was made. No abdominal mass was palpable. The child developed diarrhoea, but gradually improved with supportive therapy.

Investigations revealed the following: haemoglobin 6·7 g per cent, serum proteins 5·8 g per cent (mean), serum bilirubin <0·5 mg/100 ml, serum alkaline phosphatase 37 i.u./100 ml, prothrombin time 18 seconds (control 14 seconds), urine normal.

On tapping the abdomen straw-coloured ascitic fluid was withdrawn. The ascites was treated by paracentesis and diuretics, and gradually decreased. The haemoglobin was raised by whole blood transfusion on two occasions, and vitamin K was given to correct the prothrombin level. As the ascites decreased a mass, measuring about 7 × 10 cm, was felt in the left upper abdomen. At this point the possibility of an intra-abdominal malignancy was raised. A barium enema examination at this time showed downward displacement of the transverse colon.

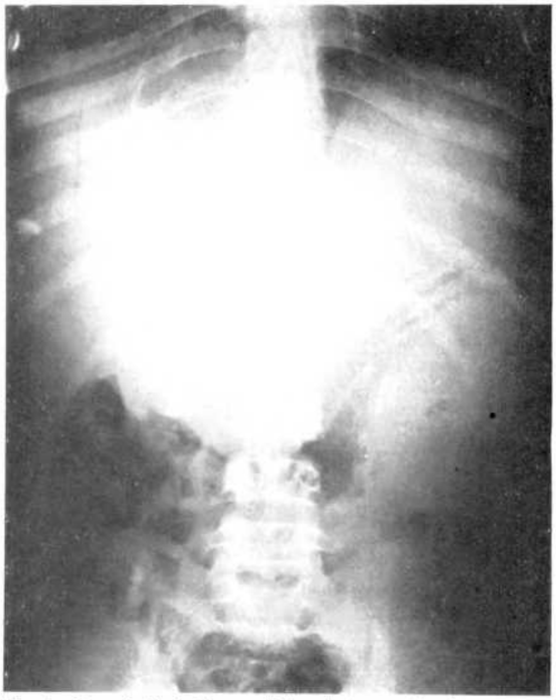

Fig. 1. *Case* 2. Plain X-ray of the abdomen showing pancreatic calcification.

As the cause of the ascites was not established a laparotomy was carried out. A pancreatic pseudocyst was present arising from the body of the pancreas. It was unilocular and contained nearly a litre of fluid. It pushed the stomach forwards and upwards, and the transverse colon downwards. A posterior cystogastrostomy was carried out. The child made a slow but uneventful recovery and was discharged 3 weeks later.

Case 2: A 12-year-old Munyoro boy was well until 5 months before admission. He had gradually developed abdominal pain, usually generalized, but occasionally radiating through to the back. It was sometimes colicky in nature. He also had had occasional episodes of diarrhoea.

In the week before admission he had had constant severe abdominal pain associated with anorexia, vomiting and loss of weight. There was no history of trauma. An upper abdominal swelling had been noticed by the patient for 3 weeks before admission. It was present in the epigastrium and extended to both hypochondria.

Present address of S. P. Master: Royal Victoria Hospital, Halifax, Nova Scotia.

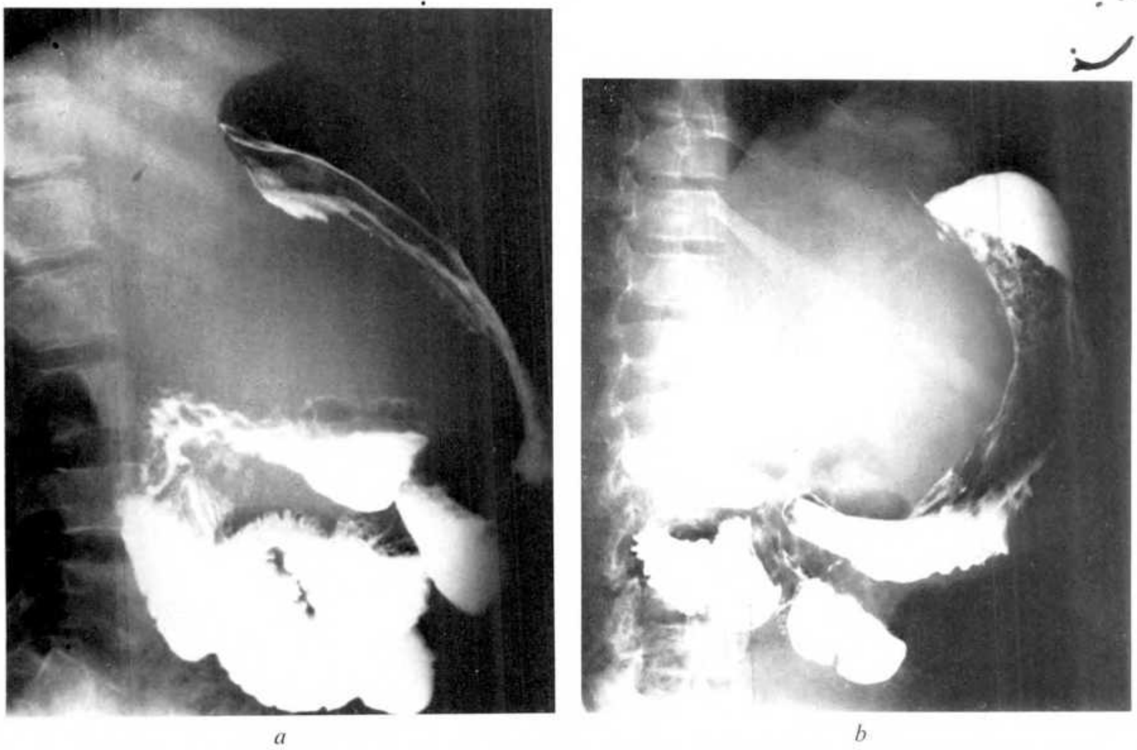

Fig. 2. *Case* 2. Barium meal films showing anterior displacement of the stomach (*a*) anteriorly and (*b*) to the left and a curved impression in the lesser curvature.

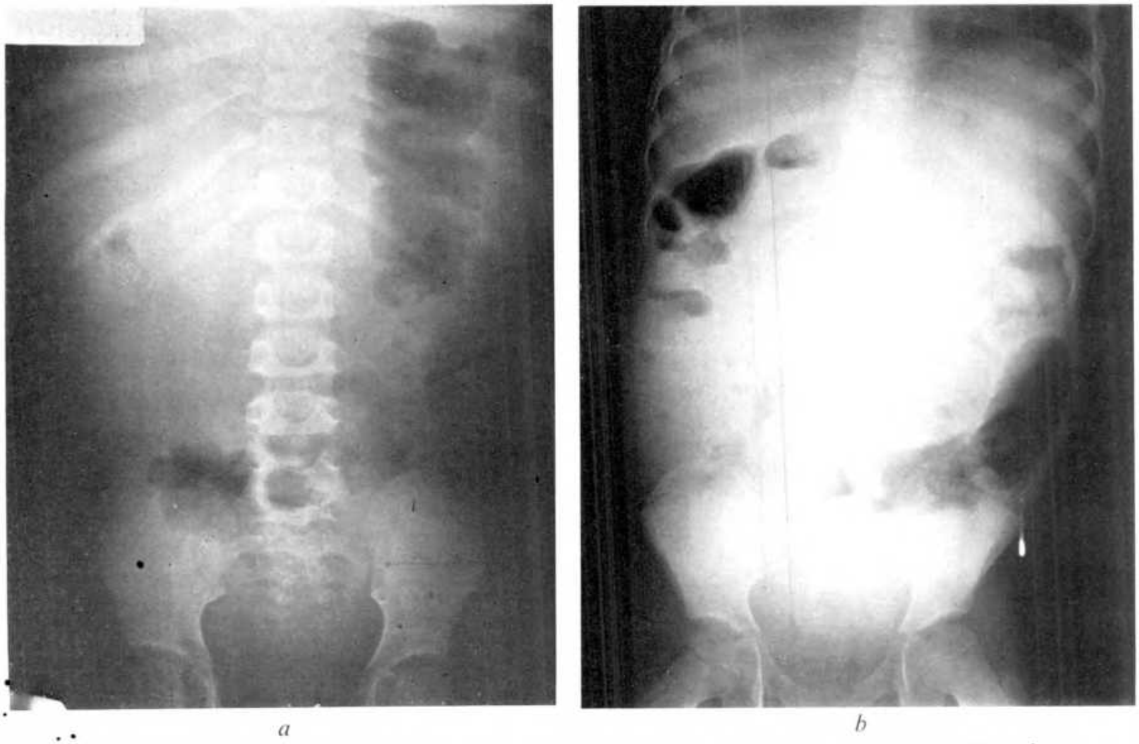

Fig. 3. *Case* 3. Plain X-rays of the abdomen showing displacement of the stomach upwards and of the transverse colon downwards.

On examination the patient was wasted. He had a large tender mass in the epigastrium and dilated veins in the upper abdomen. The spleen was enlarged. There was no ascites.

Investigations revealed the following: haemoglobin 13·6 g per cent, serum proteins 7·1 g per cent, serum bilirubin 0·5 mg/100 ml, serum alkaline phosphatase 97 i.u./100 ml, α-fetoprotein negative, serum amylase 800 Somogyi units/100 ml, WBC 5600/mm^3. A plain X-ray of the abdomen showed pancreatic calcification (*Fig.* 1). A barium meal examination showed displacement of the stomach forwards and to the left (*Fig.* 2).

A laparotomy was carried out. There was a large unilocular pancreatic pseudocyst containing a litre of bloodstained fluid. The cyst presented in the lesser sac and was pushing the stomach forwards. A posterior cystogastrostomy was fashioned. The child made an uneventful recovery. A postoperative glucose tolerance curve was normal. When seen at follow-up 3 months later the patient was in good health.

Case 3: A 5-year-old Muganda girl, weighing 16 kg on admission, had had a febrile illness, diagnosed by the mother as measles, a month before admission. A few weeks after this she had gradually developed abdominal pain. She was constipated, but had not vomited. She also had backache. There was no history of trauma.

On admission to hospital the patient was in a fair general condition. She was afebrile. Her abdomen was uniformly distended, and there was some ascites. There was a large tender swelling in the left hypochondrium extending to the epigastrium.

Investigations revealed the following: haemoglobin 7·9 g per cent, serum proteins 7·4 g/100 ml, serum bilirubin 0·5 mg/100 ml, serum alkaline phosphatase 85 i.u./100 ml, serum amylase on 25 October 1971, 274 Somogyi units/100 ml, and on 2 November, 415 Somogyi units/100 ml, blood urea 30 mg/100 ml. Specimens of stool contained no parasites. A plain X-ray of the abdomen showed an upper abdominal mass with displacement of the stomach upwards and the transverse colon downwards (*Fig.* 3). A barium meal study confirmed this.

The anaemia was corrected by whole blood transfusion. At laparotomy there was a unilocular pseudocyst, measuring 22×22 cm, of the body of the pancreas in the lesser sac pushing the stomach forwards. It contained about 2 litres of fluid. A posterior cystogastrostomy was fashioned with a 5-cm diameter stoma. A biopsy was taken which showed changes compatible with a pseudocyst of the pancreas. The patient made an uneventful recovery. A postoperative barium meal examination showed no reflux through the stoma.

Case: 4: A 9-year-old Munyarwanda boy had been ill for 8 months. He had abdominal pain, abdominal distension and anorexia and weighed 18 kg on admission. There was no history of abdominal trauma.

On admission the patient was in a poor general state. He was thought initially to have ascites, but on further examination the swelling was found to be due to a large central abdominal cyst. The cyst had a fluid thrill and extended into the left loin. It did not move on respiration. There was no ankle oedema or ascites.

Investigations revealed the following: haemoglobin 10·4 g per cent, serum proteins 7·4 g/100 ml, serum amylase 120 Somogyi units/100 ml, blood urea 28 mg/100 ml, prothrombin time 14 seconds (control 12 seconds), WBC 10 000/mm^3, ESR 99 ml/h. Examination of a stool showed no excess fat present. The urine revealed no glycosuria.

It was felt that pancreatic pseudocyst was a likely diagnosis, and the patient was prepared for operation. The abdomen was opened by a transverse supra-umbilical incision. A large cyst was present filling most of the abdomen. It pushed the stomach upwards and the transverse colon downwards. It arose from the distal part of the body of the pancreas from an area about 4 cm across. The cyst was dissected free and was removed intact. It weighed 3·6 kg and had an amylase content of 180 Somogyi units/100 ml. There was a bare area of the distal part of the body of the pancreas present at the end of the operation. The abdomen was not drained. Because of the possibility of postoperative pancreatitis, the patient was given probanthine postoperatively. The child made an uneventful recovery and was discharged 13 days after operation.

Histology confirmed the diagnosis of pancreatic pseudocyst. The child was seen 3 months after operation. He was in good health and had gained weight.

Diagnosis

The presentation of these cases did not differ significantly from that described in children elsewhere. Abdominal pain was the presenting symptom in *Cases* 2, 3 and 4, while failure to thrive was the main complaint in *Case* 1. Three of the children (*Cases* 1, 2 and 4) weighed less than expected for their ages. In 3 instances an epigastric mass was palpable on admission, and in the fourth (*Case* 1) the mass became palpable after paracentesis.

The serum amylase level was not very helpful in the diagnosis of this condition. It was raised in *Cases* 2 and 3 and was normal in *Case* 4, normal values in Ugandan African adults being 209 ± 63 Somogyi units/100 ml (Mugondi, 1971). A plain X-ray of the abdomen was found useful. All the cases showed the presence of an epigastric mass or opacity with displacement of the stomach. *Case* 2 also showed pancreatic calcification. Barium studies confirmed the stomach displacement. In *Case* 2 the stomach was displaced anteriorly and to the left, and in *Case* 1 the transverse colon was displaced downwards.

Treatment

Case 1 was in a poor nutritional state and required extensive preoperative preparation including blood transfusion and vitamin K. Apart from this no specific preoperative therapy was required. Three of the 4 cases were treated in a similar manner. As soon as the patient was fit, an exploratory laparotomy was carried out during which the diagnosis was established. A posterior cystogastrostomy was carried out. Owing to the relatively dense adherence of the cyst wall to the stomach in all 3 cases this was a straightforward procedure and caused no technical difficulties. Theoretically this may be followed by reflux of gastric contents into the pseudocyst. This may then cause bleeding or reactivation of the pancreatitis. However, this did not occur in any of the cases described here. A barium meal film taken 3 weeks postoperatively in *Case* 3 showed normal stomach appearances with no evidence of reflux into the cyst.

Case 4 had a simple excision of the cyst with no untoward complications.

Comment

It has been reported that the commonest cause of pancreatic pseudocyst in children is pancreatitis following blunt abdominal trauma (Mustard et al., 1969), but many of these cases came from North America. In none of the cases presented here was there such a history. Although pancreatitis is not common in children it does occur, and cases of pancreatitis in African children have been described by Collins (1958) and Owor (1972). Adults in Uganda not infrequently suffer from pancreatitis, which may proceed to pancreatic calcification and diabetes mellitus. It is presumed that a preceding pancreatitis was responsible for the pancreatic calcification seen radiologically in *Case* 2.

Of new diabetic patients presenting at Mulago Hospital, 7·6 per cent have radiological pancreatic calcification, without evidence of active pancreatitis (Shaper, 1964). In the present series, however, *Case* 2 had a normal glucose tolerance curve postoperatively, and there was no evidence of diabetes mellitus.

Even if it is assumed that there was a preceding pancreatitis in these children the aetiology of the pancreatitis is open to speculation. The onset of the disease in *Case* 2 was related to a febrile illness diagnosed by the mother as measles. This may be no more than coincidental and may have been some other viral disease. Cases of pancreatic pseudocyst have followed other viral diseases such as mumps (Oeconomopoulos and Lee, 1960) and Coxsackie virus (Veghelyi, 1950).

Case 1 also had some interesting features preceding the appearance of the pseudocyst. On admission he had many of the signs of kwashiorkor. Cases of pancreatic pseudocyst following kwashiorkor pancreatitis have been described (Udekwu et al., 1965), but they are uncommon. Many cases of kwashiorkor are seen in Kampala, but pancreatitis is not a common complication among these patients. The pancreatic changes in kwashiorkor are usually in the direction of atrophy (Davies, 1948) and reduction in pancreatic digestive enzymes (Thompson and Trowell, 1952). These two factors would appear to make pancreatitis less likely to occur in children with kwashiorkor.

Chronic pancreatic disease is a major cause of malabsorption in adults in Uganda (Banwell et al., 1967), and *Case* 1 may have been suffering initially from chronic pancreatic disease. The resulting malabsorption would produce some of the clinical features of kwashiorkor or congestive heart failure or cirrhosis. There was, however, no radiological evidence of malabsorption. None of the children had biliary disease or a history of alcoholic ingestion.

There are several points which are perhaps worth making. Pancreatic pseudocyst may be commoner than generally believed among children in tropical Africa. It may present in such children as an ascites of unknown origin (Hendren, 1965). The serum amylase may not be greatly elevated in this condition.

Aetiologically, the factors precipitating the possible initial pancreatitis in these children are not clear. The role played by viruses and malnutrition may be important.

Diagnosis, clinical course and treatment of acute dermal gangrene

I. McA. LEDINGHAM AND M. A. TEHRANI*

SUMMARY

Twenty patients with acute dermal gangrene following surgery, trauma or sepsis are described. In 12 the skin became gangrenous secondary to a necrotizing process affecting the subdermal fascia, and in 8 the condition arose primarily in the skin. In the first group mortality was high unless radical excision of the necrotic fascia was performed at an early stage; in 3 of the recent patients the overlying skin was removed, defatted and stored for later grafting. In the second group, incision and adequate drainage combined with antibiotics seemed to suffice. Hyperbaric oxygen was of dubious value in the first group but appeared to contribute to arrest of the lesion in the second group.

ACUTE dermal gangrene, although relatively rare in modern surgical practice, can be very alarming. The rarity of the condition not infrequently causes delay in diagnosis and treatment, with the result that the mortality remains high. The multiplicity of terms used to describe variants of the condition further complicates understanding of the clinical problem (Meleney 1933; Crosthwait et al., 1964).

With the advent of hyperbaric oxygen therapy, centres possessing hyperbaric facilities have tended to attract patients with various types of dermal gangrene on the basis that hypoxia and infection contribute to the progressive nature of the condition. Over the past 9 years a number of such patients have been referred to the Hyperbaric Unit at the Western Infirmary, Glasgow, and it is the purpose of this paper to present the accumulated clinical experience and to analyse the possible therapeutic implications, including the role of hyperbaric oxygen.

The confusing terminology which exists in the current literature prompted the authors to simplify the classification of these conditions into two categories. Thus, the term 'necrotizing fasciitis' (Wilson, 1952) has been used to describe a progressive, usually rapid, necrotizing process affecting the subcutaneous fat, the superficial fascia and the superior surface of the deep fascia. The skin is initially intact but becomes gangrenous secondary to interruption of its deep blood supply. 'Progressive bacterial gangrene' describes a more slowly progressive lesion affecting the total thickness of skin but not involving deep fascia; pus formation is variable. In the patients of both categories almost all the lesions followed wounds or sepsis of the abdominal wall or perineum, although in some cases there was extensive spread to involve other areas of the body. No patient in whom bacteriological culture revealed a predominant growth of clostridial organisms was included.

Patients and methods

The period of study extended from 1965 to 1974. Twenty patients were included in the series. Twelve were suffering from necrotizing fasciitis and 8 from progressive bacterial gangrene. Fourteen patients were referred from various parts of the United Kingdom and the remainder were from the surgical units of the Western Infirmary.

The bacteriological, haematological and pathological laboratories were extensively used in the investigation and assessment of treatment of these patients. Medical and surgical care varied with the nature of the underlying disease process but most patients received hyperbaric oxygen at some stage of their illness. The general condition of several of the patients was serious enough to necessitate care in the Intensive Therapy Unit of the hospital (after 1967). Prolonged rehabilitation was required in a few of the survivors and it was the usual practice for this phase of the patient's care to be conducted by the referring clinician.

Clinical course, investigations and treatment

The principal clinical details are summarized in *Table I* under the headings 'Necrotizing fasciitis' and 'Progressive bacterial gangrene'.

Necrotizing fasciitis: This condition followed drainage of ischiorectal sepsis (6 patients), abdominal surgery (2 appendicectomies, 1 closure of perforated duodenal ulcer, 1 Polya gastrectomy), fracture of the pelvis (1 patient) and diabetic peripheral vascular disease (1 patient). The mean age of the patients was 49 years (range 18–73 years). Five of the patients had pre-existing systemic disease including diabetes mellitus (2 patients), actinomycosis, rheumatoid arthritis/steroid therapy and carcinomatosis.

The condition sometimes presented with non-specific redness, swelling and oedema around the primary wound or area of sepsis. In other instances the first sign was the appearance of cellulitis in an area some distance from the primarily affected region, the latter itself retaining a normal appearance. When incision was not performed at this stage the process became rapidly progressive and small areas of the skin became dusky, then blue with blister formation. Finally, overt gangrene of skin occurred, revealing in due course the characteristic grey, ragged and stringy appearance of the underlying fascia. The fascial involvement was always much more extensive than that of the related skin (*Fig.* 1). The average duration

Table I: CLINICAL FEATURES OF ACUTE DERMAL GANGRENE

Case no.	Age	Sex	Site involved	Predisposing factors	Major associated factors
Necrotizing fasciitis					
1	50	M	Right flank, right lower limb	Actinomycosis in right iliac fossa, Polya gastrectomy	Septic shock, respiratory failure, disseminated intravascular coagulation, heptocellular damage
2	63	M	Right lower abdomen, upper thighs, penoscrotal	Transrectal biopsy of cancer of prostate	Toxaemia
3	54	F	Thorax, right flank, perineum	Appendicectomy (acute appendicitis)	Peritonitis, septic shock, respiratory failure
4	59	F	Anterior abdominal wall, left buttock	Left ischiorectal abscess, diabetes	Toxaemia, bronchopneumonia
5	54	M	Both flanks, perineum, scrotum, both legs, left groin	Left ischiorectal abscess, perforated sigmoid diverticulitis	Faecal peritonitis, septic shock, respiratory failure, renal failure
6	73	M	Lower abdominal wall, groin, left buttock, thigh, scrotum	Left ischiorectal abscess	Toxaemia, congestive cardiac failure
7	39	F	Left lower limb	Gangrene of left leg—below-knee amputation, diabetes	Toxaemia, dehydration, respiratory failure
8	67	F	Right flank, right iliac fossa	Perforated duodenal ulcer, closure of perforation	Toxaemia, myocardial infarction, rheumatoid arthritis, steroid therapy
9	48	M	Left thigh, left leg	Left ischiorectal abscess, carcinoma of rectum, liver secondaries	Peritonitis, septic shock, subphrenic abscess, bronchopneumonia
10	18	F	Thoraco-abdominal dorsolumbar region	Appendicectomy, acute appendicitis	Septic shock, respiratory failure, disseminated intravascular coagulation, caecal fistula
11	44	M	Anterior abdominal wall, perineum	Anal fissure, left ischiorectal abscess	Toxaemia
12	18	F	Left leg and thigh, left lower abdomen	Fractured pelvis	Toxaemia, acute pulmonary oedema, disseminated intravascular coagulation
Progressive bacterial gangrene					
1	78	M	Lower abdomen	Left orchidectomy	Toxaemia
2	70	F	Left leg	Diabetic gangrene, left below-knee amputation	Toxaemia, respiratory failure
3	77	F	Abdominal wall, upper right thigh	Diabetes, fractured neck of femur	Toxaemia, hypostatic pneumonia, pulmonary embolism, obesity
4	23	F	Right lower abdomen, right groin, perineum	Lymphopoenia, biopsy of lymph node in right groin	Toxaemia, renal failure
5	27	M	Left iliac fossa, left buttock	Road traffic accident, laceration of left buttock	Toxaemia
6	50	M	Penoscrotal region	Urethral stricture	Septic shock, respiratory failure, obesity
7	52	M	Perineum, scrotum	Left ischiorectal abscess	Toxaemia, atherosclerotic heart disease
8	38	M	Lower abdomen, left groin	Left ischiorectal abscess, diabetes	Toxaemia, relapsing pancreatitis

Table II: TREATMENT AND CLINICAL COURSE OF ACUTE DERMAL GANGRENE

Case no.	Treatment: General	Treatment: Local	Initial response to treatment	Arrest of lesion	Outcome, cause of death
Necrotizing fasciitis					
1	Antibiotics, i.v. fluids	Multiple incisions, antibiotics, OHP (3 d)	Good	No	Died (day 4). Pulmonary embolism. No post-mortem
2	Antibiotics, i.v. fluids	Multiple incisions, OHP (2 d)	Good	No	Died (day 28). Overwhelming toxaemia. No post-mortem
3	Antibiotics, i.v. fluids	Exploration of wound, OHP (3 d)	Poor	No	Died (day 16). Bronchopneumonia/peritonitis
4	Antibiotics, i.v. fluids, transverse colostomy	Multiple incisions, OHP (1 d)	Fair	No	Died (24 hours). Aspiration pneumonitis
5	Antibiotics, i.v. fluids, laparotomy, transverse colostomy	Multiple incisions, excision of necrotic fascia, OHP (8 d)	Good	Yes	Died (day 17). Renal failure, bronchopneumonia
6	Antibiotics, i.v. fluids	Multiple incisions, excision of necrotic fascia, OHP (6 d)	Good	Yes	Survived
7	Antibiotics, i.v. fluids	Desloughing, above-knee amputation, OHP (9 d)	Fair	No	Died (day 30). Overwhelming toxaemia
8	Antibiotics, i.v. fluids	Multiple incisions, OHP (4 d)	Good	No	Died (day 18). ? Pulmonary embolism. No post-mortem
9	Antibiotics, i.v. fluids, colostomy	Multiple incisions, excision of necrotic fascia and skin, OHP (2 d)	Good	Yes	Died (day 14). Bronchopneumonia
10	Antibiotics, i.v. fluids, assisted ventilation	Multiple incisions, excision of necrotic fascia and skin, multiple skin grafts	Good	Yes	Survived
11	Antibiotics, i.v. fluids, transverse colostomy	Multiple incisions, excision of necrotic fascia and skin, multiple skin grafts	Good	Yes	Survived
12	Antibiotics, i.v. fluids, transverse colostomy	Multiple incisions, excision of necrotic fascia and skin, multiple skin grafts	Good	Yes	Survived
Progressive bacterial gangrene					
1	Antibiotics, i.v. fluids, steroids	Antibiotics, OHP (7 d)	Good	Yes	Survived
2	Antibiotics, i.v. fluids	Excision of necrotic tissue, above-knee amputation, OHP (3 d)	Good	No	Died (day 22). Overwhelming toxaemia
3	Antibiotics, i.v. fluids	OHP (4 d)	Good	Yes	Died (day 11). Pulmonary embolism
4	Antibiotics, i.v. fluids	Antibiotics, OHP (7 d)	Good	Yes	Died (day 18). Massive bleeding from oropharynx
5	Antibiotics, i.v. fluids colostomy	Incision	Good	Yes	Survived
6	Antibiotics, i.v. fluids suprapubic cystostomy	Excision of necrotic tissue, skin graft	Good	Yes	Survived
7	Antibiotics, i.v. fluids	Multiple incisions, excision of necrotic tissue	Good	Yes	Survived
8	Antibiotics, i.v. fluids	Multiple incisions, excision of necrotic tissue, OHP (5 d)	Good	Yes	Survived

OHP, hyperbaric oxygen.

of time between the initiating factor and the first signs involving skin was 11 days (range 6–31 days). Coincident with the local features of progressive infection the general condition of the patient deteriorated, and toxaemia, dehydration and mental apathy rapidly ensued. In all 6 patients in whom analysis of plasma proteins was carried out hypo-albuminaemia and hypergammaglobulinaemia were found.

In 10 of the 12 patients detailed bacteriological analyses were made on specimens obtained through fresh incisions in the affected area. The commonest organisms isolated were coliforms in combination most frequently with enterococci (5) and streptococci (4); in only one case was the streptococcus of the alpha-haemolytic variety. Other associated organisms included bacteroides (3), diphtheroids (2), *Clostridium welchii* (2), proteus (2), staphylococci (1) and *Pseudomonas pyocyanea* (1). After the initial surgical incisions had been made, bacteriological cultures most regularly revealed a mixed growth of coliforms and proteus or

Ps. pyocyanea organisms, although numerous other organisms occurred as single isolates.

Because of the frequency and severity of toxaemia and dehydration, treatment aimed at improving the general condition of the patient was often as immediately important as treatment of the local infection. Thus, the administration of intravenous fluids and large doses of the appropriate systemic antibiotics was routine; penicillin or ampicillin and a broader spectrum antibiotic (usually gentamicin) formed the most frequent combination, although other antibiotics were added as indicated. Colostomy was performed in 5 patients to limit contamination of the infected area with bowel contents (and caecal fistula occurred spontaneously in a sixth).

Treatment directed at the infection itself changed during the course of the study (*Table II*). In 5 of the earlier patients (*Cases* 1, 2, 3, 4 and 8) multiple incisions were made in the affected areas and hyperbaric oxygen at 2 atm abs was administered intermittently over a period of 3 days (range 1–4 days). The response to this combined treatment was initially good in 3 patients, fair in one and poor in another. However, all 5 patients died. Death was sudden in 3 cases (on days 2, 4 and 18) with the clinical features of pulmonary embolism, and gradual in 2 with progressive toxaemia. In 6 of the later patients (*Cases* 5, 6, 9, 10, 11 and 12) radical excision of the necrotic fascia (all 6 patients) and overlying skin (4 patients) was performed; 3 had hyperbaric oxygen. Four of these 6 patients survived. In both the other patients the local necrotic process had been arrested and skin grafting was awaited. One died suddenly following perforation of a sigmoid diverticulum and the second was found at laparotomy to have secondary carcinomatosis. The remaining patient (*Case* 7) was a severe diabetic who showed little or no response to early conservative surgical management and became progressively toxic in spite of later radical surgery including above knee amputation. She died of overwhelming toxaemia on day 30 of her illness.

In 3 of the 4 patients (*Cases* 9, 10 and 12) treated by radical excision of skin overlying the involved area, the skin was preserved for later grafting. An illustrative example of one of these patients is outlined below:

Case 10: P. H., an 18-year-old woman, underwent an emergency appendicectomy for histologically proved acute appendicitis. Her postoperative recovery was complicated by continued pyrexia, vomiting and abdominal distension which was initially treated conservatively with no improvement. At re-exploration 3 days later the wound showed signs of cellulitis and it was noted that part of the external oblique aponeurosis was necrotic. A large purulent pelvic collection was encountered. The obviously necrotic portion of fascia was excised, and following evacuation of pus and irrigation of the pelvic cavity with noxytiolin a drain was inserted in the pelvic cavity and the wound closed loosely, leaving a subcutaneous drain. Culture from the pus revealed growth of lactose-fermenting coliform organisms and enterococci sensitive to gentamicin.

In spite of adequate drainage of the pelvic cavity and intravenous administration of the appropriate antibiotics and fluids, the patient remained very toxic, with a gradual fall in urine output and progressive anaemia. Because of lack of improvement, further exploration was carried out on day 11. This revealed gross undermining of the skin of a large area of the thoraco-abdominal wall and extensive necrosis of the subcutaneous tissue, although the skin itself appeared normal (*Fig.* 2). A diagnosis of necrotizing fasciitis with associated endotoxic shock was made. The skin and subcutaneous tissue of the involved part were completely excised (*Fig.* 3). Numerous bacteriological swabs were taken. The skin was defatted and preserved at 4 °C at the Regional Plastic Surgical Centre with a view to future grafting. The patient was transferred from the operating theatre to the Intensive Therapy Unit for subsequent care.

In the Intensive Therapy Unit considerable therapeutic, psychiatric and nursing problems were encountered. Frequent blood gas estimations revealed a gradual deterioration in pulmonary gas exchange necessitating the use of intermittent positive pressure ventilation via an endotracheal tube. The patient was dehydrated and acidotic and there was haematological evidence of disseminated intravascular coagulation. Bacteriological cultures from the denuded area revealed a heavy growth of coliform organisms and bacteroides. A caecal fistula developed which did not respond to simple closure.

With appropriate treatment the patient gradually improved and on day 16 the endotracheal tube was removed. The initially preserved skin was applied to the denuded area but little of the graft survived. Transfer to the Regional Plastic Surgical Centre was arranged on day 20 and multiple skin grafting was performed. Complete skin cover was achieved in 3 months. The appearance of the grafted areas at 1 year is illustrated in *Fig.* 4. The caecostomy was finally closed 18 months after the original appendicectomy.

In the most recent patient (*Case* 12) the skin overlying the involved area was completely excised 5 days after the onset of the condition; 80 per cent of this skin survived after grafting 1 week later.

Progressive bacterial gangrene: This form of gangrene followed ischiorectal sepsis (3 patients), lower abdominal surgery (1 orchidectomy and 1 lymph node biopsy), urethral stricture (1 patient), fractured neck of femur (1 patient) and diabetic peripheral vascular disease (1 patient). The mean age of these patients was 52 years (range 23–78 years). Five of the patients had pre-existing systemic disease including diabetes mellitus (3 patients), persistent lymphopoenia and severe atherosclerotic heart disease.

In all 8 patients bacteriological cultures were taken from fresh incisions in the affected area. The commonest organisms isolated were coliforms. Other associated organisms included bacteroides (3), *Cl. welchii* (2), haemolytic streptococci (1) and staphylococci (1). The most frequent colonizing organisms were coliforms (4) associated with proteus in 2 patients and *Ps. pyocyanea* and *Staphylococcus aureus* in 1 patient each. In one of the patients (*Case* 1) bacteriological cultures were consistently negative.

The condition usually presented with a non-specific cellulitis around the wound or near the site of sepsis. The abdominal wall lesions soon developed a characteristic appearance with a central necrotic zone, an advancing, often serpiginous, purplish zone and a peripheral erythematous margin fading gradually towards normal skin. In the case of penoscrotal lesions skin gangrene was rapidly progressive and the purplish marginal zone was not obvious. Irrespective of site, the whole skin thickness was primarily involved and there was little or no invasion of subcutaneous tissues. Unlike necrotizing fasciitis this form of acute dermal gangrene followed the initiating factor without an

apparent quiescent interval. The patient's general condition deteriorated with spread of the local infection but rarely to the same degree of severity as in the patients with necrotizing fasciitis. Hypo-albuminaemia and hypergammaglobulinaemia were marked in 3 of the 4 patients in whom analysis of plasma proteins was performed.

Treatment of the patient's general condition was of major importance and consisted of the administration of intravenous fluids and antibiotics; colostomy and suprapubic cystostomy were performed in 2 of the patients.

In 6 of the patients (*Cases* 2, 3, 5, 6, 7 and 8) it was obvious from the outset that all the layers of the skin were involved, and in these, local treatment consisted of either incision or early excision of necrotic tissue. Three of the most severely ill of these patients received hyperbaric oxygen. The initial response to the combination of treatment was good in all 6 patients although in 1 patient the lesion was not finally arrested. Four survived with complete healing of the skin lesions One patient died suddenly on day 11 from pulmonary embolism, and the other, an elderly diabetic, succumbed to progressive overwhelming toxaemia on day 22.

In 2 of the patients (*Cases* 1 and 4) the condition seemed to be limited clinically to the epidermal layers of skin, and in these, local treatment consisted of non-adherent dressings and hyperbaric oxygen. In both patients the initial response to treatment was good and the local condition was arrested. The younger patient died suddenly on day 18 after massive oropharyngeal bleeding, probably aggravated by severe thrombocytopenia. The older patient survived with spontaneous healing of the affected area.

Illustrative examples of 2 of the patients in this group are outlined below.

Case 3: G. H., a 78-year-old woman, was admitted to another hospital with a fracture of the neck of the right femur. At the time of admission the patient was noted to have a small patch of gangrenous skin in the suprapubic region which spread rapidly during the course of the next 2 days with surrounding inflammatory oedema and surgical emphysema. Bacteriological studies revealed heavy growth of coliform and bacteroides organisms.

In spite of the administration of appropriate antibiotics, her condition deteriorated. She became toxic and a rapidly spreading cellulitis was noted. Further bacteriological studies revealed a heavy growth of bacteroides, anaerobic streptococci and proteus organisms. At this stage diabetes mellitus was discovered for the first time and treatment with soluble insulin was started. Transfer to the Hyperbaric Unit was arranged on the eighth day by which time there was an extensive area of necrosis of the lower abdominal wall and upper right thigh (*Fig.* 5). Hyperbaric oxygen therapy was started at 2·5 atm abs in sessions not exceeding 2½ hours continuously. The patient's condition improved and 48 hours after hyperbaric oxygen therapy it was considered that the progress of the infection had been halted. Over the next 24 hours, however, the improvement was not sustained and the patient died suddenly on the eleventh day. A post-mortem examination revealed organizing ante-mortem thrombi in the pulmonary arteries.

Case 1: W. W., a 78-year-old man, underwent a left orchidectomy through an inguinal incision for a benign testicular mass. Six days later an ischaemic lesion appeared in the wound. In spite of local treatment the lesion extended over the lower abdomen during the next few days, and at the time of admission to the Western Infirmary (day 22) the greater part of the left lower quadrant of the abdomen was involved (*Fig.* 6*a*). An incision into the affected area suggested that the deeper layers of the skin and subcutaneous tissues were not involved in the process, but histological examination of biopsy material indicated some spread to deeper layers.

The initial bacteriological studies failed to reveal any growth, an observation which was confirmed on ten subsequent wound cultures. The patient was subjected to an intensive course of hyperbaric oxygen over the next week. In addition, parenteral and local antibiotics were administered in spite of the negative bacteriological reports. The patient's progress following this combined therapy was satisfactory and gradual spontaneous epithelization occurred over the subsequent weeks (*Fig.* 6*b*).

Discussion

The clinical conditions described in this study readily fell into two categories: one in which skin gangrene succeeded a major infective process in the subcutaneous tissues, and the other in which skin gangrene related directly to infection of the skin.

Necrotizing fasciitis

The first of these two clinical conditions was described many years ago (Meleney, 1924), but the term 'necrotizing fasciitis' was not used until relatively recently (Wilson, 1952). The term is appropriate since the primary condition is a progressive necrosis of the superficial fascia, subcutaneous fat and superior surface of the deep fascia with death of skin secondary to thrombosis of the subcutaneous blood vessels. Tissues deep to the fascia are not normally involved.

The diagnosis of necrotizing fasciitis is not difficult to establish once the characteristic necrotic appearance of the fascia is visualized, but in the early stages the relatively normal appearance of the skin conceals the severity and extent of the underlying disease. The diagnosis can only be confirmed with certainty by immediate exploratory incisions. The condition is readily distinguished from 'gas gangrene' which normally occurs in association with penetrating wounds following major trauma and involves, in its florid form, invasion of muscle by clostridia organisms. Crepitus and a 'mousy' smelling discharge are characteristic. The patient becomes rapidly toxic and is often restless and delirious.

Although the original description of necrotizing fasciitis has survived the passage of time some of the features of the condition appear to have changed. In some, predominantly early, reports (Meleney, 1924, 1933; Wilson, 1952; Strasberg and Silver, 1968) the disease commonly occurred in the extremities, often after minor trauma, whereas in several recent publications (Rea and Wyrick, 1970; Wilson and Haltalin, 1973) the trunk, and in particular the lower abdomen, was the most commonly affected site. The bacteriological pattern appears also to have undergone a change with the passage of time. In Meleney's (1924) series haemolytic streptococci were exclusively isolated, but later the bacterial flora included haemolytic staphylococci (Wilson, 1952) and various Gram-negative organisms (Crosthwait et al., 1964; Meade and Mueller, 1968; Rea and Wyrick, 1970). In the present series the bacteriological cultures taken directly from the necrotic fascia through freshly incised wounds revealed a wide variety of organisms. In all but one case haemolytic streptococci were absent. Two factors may have prevented the demonstration of these organisms on bacteriological culture: the early use of antibiotics, including topical applications, prior to consideration of the diagnosis of necrotizing fasciitis, and rapid overgrowth with essentially faecal organisms in wounds predominantly of the lower abdomen and perineum. Nevertheless, it is surprising that only one isolate of haemolytic streptococci was made, and it is possible that while these organisms may be important in initiating the disease process, their presence may not be critical for its subsequent progression.

The effect of treatment also appears to have changed over the years. In early reports, incision of the affected area together with frequent antiseptic soaks and careful débridement of necrotic tissue was attended by excellent results, with the reported mortality as low as 9 per cent (Wilson, 1952). Nowadays such relatively conservative procedures appear less effective unless used at a very early stage, and mortality in some series ranges between 30 and 40 per cent (Crosthwait et al., 1964; Rea and Wyrick, 1970; Wilson and Haltalin, 1973). It is possible that only the most resistant infections are now reported and that infections involving the extremities in young, otherwise healthy individuals respond rapidly to incision, débridement and antibiotics. Infections of the trunk and perineum are more difficult to drain adequately and diagnostic incisions may be delayed in the elderly or very sick patient. On the basis of present experience the best results appear to follow early, multiple and extensive incisions into the affected area with complete excision of the underlying necrotic fascia. Whether the large flaps of skin thus created should simply be reflected or excised and stored is debatable, but if there is any doubt about the adequacy of drainage the latter alternative is preferable and is best done at one operation. This policy was adopted in 4 of the most recent patients and the excised skin later regrafted in 2.

The role of hyperbaric oxygen in the treatment of this condition is uncertain. The patient's general condition normally improved after hyperbaric oxygen but the latter was usually only one of the therapeutic changes introduced on initial referral. Other factors, e.g. alterations in the antibiotic regimen or in intravenous fluid administration, may have played an equally important role. Certainly hyperbaric oxygen did not halt spread of the necrotic process in patients whose skin flaps were not reflected. This pattern of response to hyperbaric oxygen was readily distinguishable from that in most patients with 'gas gangrene' treated at this centre in whom hyperbaric oxygen combined with simple incision is usually associated with rapid cessation of the primary condition. The patient with the most extensive involvement (*Case* 10) survived because of the radical nature of the surgical procedure; she did not have hyperbaric oxygen treatment. Present experience would suggest, therefore, that surgical treatment is of prime importance. Whether hyperbaric oxygen adds anything to surgical management remains to be determined. Antibiotics were usually administered early in the course of the illness and appear to have been the appropriate choice in most cases. Like hyperbaric oxygen, however, the role of antibiotics seems to be secondary to radical surgical treatment.

Progressive bacterial gangrene

The conditions included under this heading have in the past been considered as separate clinical entities. For example, 'postoperative progressive synergistic gangrene' was so called because lesions answering the clinical description of 4 of the patients in the present series (*Cases* 1, 3, 4 and 5) appeared to be caused by a pair of organisms which were more active in combination than alone. Originally the pair most frequently incriminated were a non-haemolytic microaerophilic streptococcus and *Staph. aureus* (Meleney, 1933), but subsequently several synergistic pairs have been demonstrated, including proteus and *Staph. albus* (Lyall and Stuart, 1948) and coliforms and *Ps. aeruginosa* (Webb and Berg, 1966). 'Fournier's gangrene' was the original name attached to lesions similar to those described in 3 of the patients of the present series (*Cases* 6, 7 and 8). These gangrenous lesions of the scrotum and penis were considered to be due to invasion by haemolytic streptococcus (Meleney, 1933). 'Synergistic necrotizing cellulitis' might well have been the name applied to the final patient of this series (*Case* 2), in whom widespread invasion of an amputation stump was attributed to a synergistic combination of aerobic Gram-negative rods and an anaerobic streptococcus, with bacteroides as a frequently associated organism (Stone and Martin, 1972).

Recently, the justification for these separate subgroups has been questioned since they are almost certainly at most variants of a single process (Pillsbury et al., 1956; Rook et al., 1972).

Examination of the bacteriological pattern reported in the present study does not support the concept that one specific combination of organisms underlies this condition. In only one of the patients, with scrotal gangrene, did culture reveal haemolytic streptococci; the majority of the remainder of the series had a mixture of coliform organisms with one of the bacteroides or clostridial family—not an unexpected combination in wounds of the lower abdomen and perineum. Synergism between some of these groups may exist but presumably not more so than in many other wounds similarly infected.

Although there may have been historically valid reasons for separating the subgroups on the grounds of differing therapy, this does not now seem to be necessary. Whereas the earlier literature suggested the need for wide and radical excision of the affected area in the case of so-called 'progressive synergistic gangrene', in recent years simple incision and drainage combined with appropriate antibiotics in adequate doses seem to suffice. The use of hyperbaric oxygen in 5 of the 8 patients in the present series appeared to contribute to the arrest of the lesion in all but one. Apparent disappearance of the anaerobic organisms from the wounds may, in part, explain the role of hyperbaric oxygen in this condition.

General comments

Both these forms of acute dermal gangrene are relatively rare in modern surgical practice. The advent of antibiotics has presumably helped to reduce the incidence of the condition and there seems little doubt that the cases reported in the current literature represent a group in which infection is only one of the factors involved. Ischaemia and reduced host defence mechanism may be equally important factors.

In necrotizing fasciitis the relative avascularity of the fascial planes may favour the subcutaneous spread of infection, particularly with anaerobic organisms. A number of the patients had underlying systemic illness to which was added hypoproteinaemia and presumably other deficiencies as the illness progressed. The patient's ability to resist sustained infection was thus substantially reduced. In progressive bacterial gangrene avascularity of the wound and reduced host defence mechanisms appear to have contributed to the progress of the lesion in some instances, although specific immunological defects were not adequately investigated.

Thus, while earlier reports describing acute dermal gangrene stressed the importance and apparent specificity of the invading organisms, it now seems clear that the main problems confronting the surgeon is a vicious cycle of infection, local ischaemia and reduced host defence mechanisms. Which of these factors predominates in the inidividual patient will vary, but it is vital that all three are considered simultaneously if arrest of the progress of these lesions is to be achieved and lives saved.

Acknowledgements

We gratefully acknowledge the collaboration of the many colleagues, both at the Western Infirmary, Glasgow, and elsewhere in the United Kingdom, who have referred patients to us. We are also grateful to Dr J. D. Sleigh, Consultant Bacteriologist, Western Infirmary, Glasgow, who read and criticized the bacteriological component of the paper.

Gas gangrene of the extremity: the presenting clinical picture in perforating carcinoma of the caecum

R. MZABI, H. S. HIMAL AND L. D. MacLEAN*

SUMMARY

This paper reports 2 diabetic patients with perforating carcinoma of the caecum and gas gangrene of the pelvis and right lower extremity in whom the infective process was the main clinical feature.

ACCORDING to Goligher and Smiddy (1957), 7 per cent of all cases of carcinoma of the large intestine present with perforation of the bowel and either localized or generalized peritonitis. Perforation within the tumour itself leading to localized peritonitis and abscess formation is more characteristic of caecal lesions (Ewing, 1951; Patterson, 1956).

A recognized complication of carcinoma is gas gangrene (Cabrera et al., 1965), with a very high associated mortality.

Case reports

Case 1: Mrs C. J., a 71-year-old diabetic female treated with parenteral insulin, was admitted to the Royal Victoria Hospital, Montreal, with the diagnosis of acute gangrene of the right lower extremity due to atherosclerotic vascular disease. She had not been feeling well for about 1 month and on the night prior to admission had had several episodes of nausea and vomiting. On the morning of the day of admission the patient had noted pain in the right leg and foot. The pain had intensified and the patient was brought to hospital. Clinical examination revealed a pale sweating female complaining of severe pain in the right lower extremity. The blood pressure was 140/80, the pulse was 100/min and regular and the oral temperature was 38 °C. The abdomen was tense with minimal guarding and no tenderness. Re-examination of the abdomen with minimal analgesia revealed no abnormality.

The right lower extremity was cold and pale and crepitations extended from the foot to the thigh. Only the right femoral pulse was present and was normal to palpation. Urinalysis revealed 2+ glucose and there was a marked leukocytosis (25 600 ml/mm).

With the diagnosis of gas gangrene of the right lower extremity, chloromycetin 500 mg intravenously was given and the patient was taken to the operating theatre where a right supracondylar amputation was performed. During the procedure gas was noted to be present in the fascial planes. At the conclusion of the operation the patient became hypotensive and cardiac arrest ensued. Resuscitation was unsuccessful, and the patient died 4 hours after admission to hospital.

Post-mortem examination revealed a large fungating anaplastic carcinoma of the caecum which had perforated. The anterior caecal wall was gangrenous with fibropurulent peritonitis in the vicinity. *Clostridium septicum* was cultured from the wall of the caecum as well as from the stump of the right thigh. Gas gangrene was present in the muscles of the right pelvis, right thigh stump and anterior abdominal wall.

Case 2: Mrs B. F., a 78-year-old diabetic female, was admitted complaining of pain in the right hip. There was no antecedent trauma. Several years prior to admission the right fifth toe had been amputated for gangrene.

The blood pressure was 190/90, the pulse was 85/min and the oral temperature was 38·4 °C. The abdomen was soft and non-tender. The right hip was painful to movement. Urinalysis revealed 3+ glucose. Random blood sugar was 420 mg per cent. An X-ray revealed a non-displaced fracture involving the greater trochanter. The presence of gas was noted in the soft tissues of the right pelvis, hip and thigh.

Later that evening the abdomen became distended and vomiting occurred. Clinical subcutaneous emphysema appeared along the right thigh and buttock. Hypotension also developed. A diagnosis of perforated viscus was made and the patient was taken to the operating theatre. However, she died before laparotomy could be performed.

Post-mortem analysis revealed a fungating well-differentiated adenocarcinoma of the posterior wall of the caecum which had perforated. Fibrinous adhesions were present between the tumour and the right iliopsoas muscle. The right thigh muscles, including the iliopsoas muscle, were necrotic. *Clostridium tertium*, anaerobic streptococci and *Escherichia coli* were cultured from the right iliopsoas and right thigh muscles.

Discussion

Caecal carcinoma commonly presents as a triad—abdominal mass, anaemia and weight loss. Rarely, these tumours present with perforation (Ransom, 1939; Brown et al., 1948).

Gas gangrene of the extremities as the presenting initial clinical picture is exceptional. Kimball and Rawson (1952) described a patient who presented with gas gangrene of the left arm. She died prior to initiation of therapy; autopsy revealed adenocarcinoma of the caecum with retroperitoneal perforation and necrosis and crepitations of the retroperitoneal tissues. Gazzaniga (1967) reported an 81-year-old diabetic woman who presented with crepitation and pain in the right upper extremity. She was taken to the operating theatre where right arm disarticulation was performed. However, the patient died several hours later. Post-mortem examination revealed generalized haemolysis, endocarditis and myocarditis and a large and extensive adenocarcinoma of the caecum with focal ulceration, but without any evidence of perforation. Cultures from the arm grew *Clostridium welchii*. The cause of death was clostridial septicaemia.

Valentine (1957) reported a 70-year-old man who presented with pain in the left hip after a fall. He had previously been admitted to hospital because of abdominal pain with a mass in the right iliac fossa. An appendiceal abscess was diagnosed; the patient was treated conservatively and sent home with the view to interval appendectomy. Several hours after his second admission there was crepitus and bruising of the left hip. Two hours later he died. Post-mortem examination revealed necrosis and haemorrhage into the muscles of the left thigh. An ulcerating carcinoma of the caecum was also present. *C. septicum* was cultured from the necrotic muscles. Camblin and Kinley (1970) reported a 74-year-old man who presented with severe pain in the left thigh. Physical examination revealed generalized tenderness over the abdomen, maximal at the right iliac fossa. The left thigh was swollen, bruised, tender and crepitant. Laparotomy revealed a large fungating carcinoma of the caecum without evidence of perforation. A right hemicolectomy and excision of necrotic tissue in the left thigh were carried out. However, the patient died several hours later. *C. septicum* was cultured from the left thigh.

In the 4 patients described above, although cultures of the necrotic areas revealed clostridial organisms, bacteriological studies on the caecal carcinomas were not performed. Septicaemia occurred with colonization of muscles of the extremities leading to myonecrosis.

Clostridia are normal inhabitants of the digestive tract and can be easily isolated and cultured from the faeces (MacLennan, 1962). Tissue necrosis is a necessary antecedent to clostridial myositis. In the 2 case reports presented here, necrotizing carcinoma of the caecum with local infection caused an environment conducive to spread of the organisms along the retroperitoneal tissue planes including the iliopsoas muscle. The necrotizing myositis soon spread to the lower extremity which then became the main clinical problem. Similar patterns of spread have been reported complicating appendicitis (Gordon, 1936), diverticulitis (Dawson and Hardy, 1948; Nichols 1961) and carcinoma of the left colon and rectum (Wyman, 1949; Whyland and Levin, 1960). *Clostridium perfringens*, *C. septicum*, *C. novyi*, *C. histolyticum*, *C. fallax* and *C. bifermentans* under the appropriate conditions will cause tissue necrosis and myositis (MacLennan, 1962). *C. tertium*, on the other hand, does not cause gas gangrene (MacLennan, 1962), but this organism in conjunction with anaerobic streptococci and *E. coli* can lead to necrosis, as demonstrated in one of our patients.

The presence of diabetes mellitus in both patients may have played an important role in the development of tissue necrosis. Both clostridial and non-clostridial gas gangrene is more common in diabetic patients (Wills and Reece, 1960; Brightmore, 1971; Weinstein and Barza, 1973).

The main aspect in the management of these patients is an early awareness of the underlying cause. Early diagnosis and surgery of the caecal carcinoma are of prime importance. Abdominal X-rays demonstrating gas within the tissues strongly suggest gas gangrene. In patients with perforating carcinoma of the caecum and associated myonecrosis, treatment must consist of early intensive fluid management prior to the development of toxaemia and shock. Surgical therapy must include excision of the carcinoma, extensive débridement of all necrotic tissue and adequate antibiotic cover.

Wound infections due to *Bacteroides fragilis* following intestinal surgery

D. A. LEIGH*

SUMMARY

Ninety-six wound infections due to Bacteroides fragilis occurring after intestinal surgery are described. Most infections followed appendicectomy or colectomy for diverticulitis.

B. fragilis was isolated in pure growth from 47 per cent of infections, and in mixed culture the other common bacteria were Klebsiella spp., Escherichia coli and Enterobacter spp.

Fifty-three per cent of the infections responded rapidly to either non-specific measures or antibiotic therapy, but 47 per cent of patients developed complications, usually abscess formation.

The successful isolation of bacteroides from clinical material requires special precautions. The specimen for bacteriological examination must be sent to the laboratory in a transport medium which maintains an anaerobic environment and the culture techniques must include a selective agar for the isolation of anaerobic bacteria.

The role of antibiotic therapy in preventing postoperative wound infection after intestinal surgery is discussed. Bacteroides has an unusual pattern of antibiotic susceptibility and it is essential that an effective antibiotic such as lincomycin is included in the treatment of infection originating from the intestinal tract.

THERE has recently been revived interest in the importance of anaerobic bacteria and their role in postoperative infection, particularly following gastro-intestinal surgery. Anaerobic bacteria are the predominant group of organisms in the faeces and account for over 90 per cent of the total bacterial population. These bacteria are highly sensitive to aerobic conditions and changes in temperature and are difficult to isolate routinely in the laboratory unless special culture techniques are used. *Bacteroides fragilis* is the species most frequently isolated but its incidence in wound infections following intestinal surgery is not known. After appendicectomy 93 per cent of wound infections were due to bacteroides (Leigh, 1974a), and in patients with anaerobic bacteriaemia 73 per cent had underlying gastrointestinal disease (Wilson et al., 1972). Gillespie and Guy (1956) and Gunn (1956) reported that the majority of bacteroides infections followed intestinal surgery.

The successful isolation of anaerobic bacteria from surgical infections requires careful collection of the specimen and protection in a transport medium which maintains an anaerobic environment during transit to the laboratory.

This paper presents the details of a group of 96 patients who developed wound infection due to *B. fragilis* following intestinal surgery, describes the measures necessary for successful isolation and discusses the role of antibiotic therapy.

Patients and collection of specimens

All the patients included in the study were admitted for emergency or elective surgery to the intestinal tract and had developed severe wound infections which were associated with fever, pain and a purulent discharge. Swabs were taken from the wound infection and were sent to the laboratory in either Stuart's transport medium or Robertson's meat broth. Specimens of pus or purulent fluid were also collected at the time of the operation from patients with obvious intra-abdominal infection. Patients with formed abscesses at the time of surgery were excluded. Details of antibiotic therapy and the postoperative progress of the patients were obtained either from the Control of Infection records or the inpatients' notes. All wound infections were inspected by the Control of Infection sister.

The outcome of the infection was considered successful when there was a rapid response to either antibiotic therapy or non-specific therapeutic measures. Complications were present when an abscess developed from the initial infection or the infection persisted despite appropriate therapy.

Laboratory techniques

The specimens were examined as soon as possible after arrival in the laboratory. All the swabs were cultured on to simple blood agar, MacConkey's agar, a selective blood agar plate containing 0·01 per cent neomycin, haemin 5 μg/ml and vitamin K 0·2 μg/ml and into Robertson's meat broth. The plates were incubated aerobically and anaerobically using the Gaspak (BBL, Maryland) method and examined at 24 and 48 hours. Subculture from the Robertson's meat broths was carried out on to a similar set of agar plates. The strains of *B. fragilis* were identified by routine bacteriological methods (Cowan and Steel, 1965), and antibiotic sensitivity tests were carried out by the impregnated disc technique.

Results

The primary site of surgery and probable source of the 96 *B. fragilis* infections is shown in *Table I.* Sixty-one of the wound infections were associated with appendicectomy, and in 37 perforation of the appendix had occurred. Four infections followed an elective appendicectomy carried out in association with other surgical procedures. There were 4 infections following

surgery to the ileum, 3 of which were in patients with Crohn's disease. Thirty-one infections followed operations on the large intestine; 16 in patients with diverticulitis including 6 where perforation of a diverticulum had occurred, and 12 where carcinoma was found.

Table I: SOURCE OF INFECTION IN 96 PATIENTS

Site of surgery	Disease	No. of cases	
Appendix	Acute appendicitis	20	61
	Perforated appendicitis	37	
	Routine appendicectomy	4	
Ileum	Ischaemia	1	4
	Crohn's disease	3	
Colon and rectum	Ischaemia	3	31
	Diverticulitis	10	
	Perforated diverticulitis	6	
	Carcinoma		
	Caecum	1

1971	1272	145	11	20	14
1972	1380	155	11	35	22
1973	1328	200	15	120	60

* Approximate total

In 26 (27 per cent) of the 96 patients who developed wound infection, swabs taken at the time of surgery grew the bacteria later responsible for the wound infection.

B. fragilis was isolated in pure growth from 44 (47 per cent) of the infections. Where a mixed growth was present (*Table II*) the commonest associated organism was *Klebsiella* spp. (40 per cent). A pure growth was found more frequently where carcinoma was present (83 per cent), and less commonly where perforation of the appendix (29 per cent) or large bowel (40 per cent) had occurred.

Fifty-one (53 per cent) of the wound infections responded rapidly either without specific therapy or with antibiotic therapy. Forty-five (47 per cent) patients developed complications, usually wound abscess or metastatic abscesses such as subphrenic or pelvic, and 1 patient died of the infection. The incidence of complications was highest (70 per cent) in diverticulitis (*Table III*). Where complications developed a *B. fragilis* infection had been diagnosed at the time of surgery in 33 per cent of patients.

Forty-six of the patients received chemotherapy but in only 21 was the antibiotic given effective against bacteroides. Ten patients received either clindamycin or lincomycin, 5 tetracycline and the remainder either co-trimoxazole or metronidazole. Where ineffective treatment was prescribed 20 patients received ampicillin, 7 kanamycin, 4 cephaloridine and 3 co-trimoxazole. In several cases combined therapy was given.

Antibiotics were more commonly prescribed at the time of the operation when perforation of the intestine had occurred, but in many cases treatment was only given after the wound infection had developed.

In this retrospective analysis antibiotic therapy did not appear to improve the rate of recovery or reduce the incidence of complications.

The increase in the incidence of isolation of *B. fragilis* from postoperative wound infections following major intestinal surgery is shown in *Table IV*. Although the incidence of all wound infections rose only slightly between 1970 and 1973, the isolation rate of *B. fragilis* increased from 13 to 60 per cent. The increase in the isolation rate was due mainly to the use of special transport media which protected the bacteria present on the swab during delivery to the laboratory. In addition the swab was inoculated on to a special selective culture medium which contains neomycin to inhibit other bacteria.

Discussion

Infections due to *B. fragilis* occur most frequently after intestinal surgery (Gillespie and Guy, 1956), and in the Wycombe and Amersham Hospitals 67 per cent followed operations on the small and large bowel. In addition, where bacteroides organisms were isolated from abscesses 78 per cent of these had originated from the intestine. In this study the majority of wound infections followed appendicectomy, but this is probably only a reflection of the frequency of this operation.

All the wound infections were associated with severe inflammation, a purulent discharge and fever. There was frequent necrosis of the skin edges of the operative wound and in a few cases the suture line burst. Bacteria were isolated in large numbers and *B. fragilis* was always present in the highest count and was usually seen as the predominant organism in the Gram film. There was no clinical doubt that the wound was infected and not simply colonized in the superficial layers by bacteria.

B. fragilis was isolated in pure culture in nearly 50 per cent of the wound infections. In the past the incidence of sterile swabs from clinically infected wounds has been a common finding and there is little doubt that in many of these patients anaerobic bacteria which failed to grow on culture were responsible for the infection. The high incidence of *Klebsiella* spp. and *Enterobacter* spp. in mixed cultures (*Table II*) may be a reflection of previous antibiotic therapy as these organisms are resistant to ampicillin, an antibiotic commonly prescribed. Wound infection following surgery for malignant conditions of the intestine was usually caused by a single organism, and a mixed culture was found more frequently following perforation of the intestine.

The outcome of bacteroides infections is relatively good. Only 1 patient in this series died but 47 per cent of patients developed complications which prolonged their period of hospitalization. The commonest complication was metastatic abscess formation which frequently required further surgical intervention. The development of bacteriaemia is a serious feature of bacteroides infections which can increase the mortality to over 30 per cent (Bodner et al., 1970; Wilson et al., 1972; Leigh, 1974b), but this can be controlled by the early administration of effective antibiotic therapy (Gelb and Seligman, 1970; MacKenzie and Litton, 1974).

The role of antibiotic therapy in the prevention and treatment of wound infections after surgery is not generally known. Many antibiotic and antiseptic preparations have been used locally in the wound area to prevent infections (Crosfil et al., 1969; Longland et al., 1971; Gilmore et al., 1973; Evans et al., 1974). Parenteral antibiotic therapy has been shown to reduce the development of complications but not to influence wound healing (Magarey et al., 1971). However, in patients with perforated appendicitis the incidence of wound infection was reduced from 50 to 15 per cent when lincomycin was given early in the postoperative period (Leigh, 1974a). The success of antibiotic therapy depends on the activity of the chemotherapeutic agent against the infecting organisms and the dosage in providing adequate serum and tissue concentrations. Many studies have not prescribed antibiotics with significant bactericidal activity against anaerobic bacteria, and in the group of patients reported here less than 50 per cent received an antibiotic effective against bacteroides.

Bacteroides has an unusual spectrum of antibiotic susceptibility and it is rarely sensitive to the commonly prescribed chemotherapeutic agents. It is totally resistant to the aminoglycoside group of antibiotics such as gentamicin and kanamycin, and of the penicillins, only carbenicillin has consistent bactericidal activity because of the high blood levels that are achieved on standard parenteral therapy. Tetracycline has been used effectively in the past, but recent workers (Bodner et al., 1972; Kislak, 1972; Okubadejo et al., 1973) have found nearly 40 per cent of strains resistant to easily attainable serum concentrations. Clindamycin is the most active antibiotic against bacteroides and has been used with success in the treatment of infections (Bartlett et al., 1972), but it can only be given orally, and in severe infections parenteral lincomycin is the antibiotic of choice.

There are three main difficulties associated with the diagnosis of anaerobic infections following intestinal surgery. First, the failure of the surgeon to take specimens for bacteriological examination from areas of potential infection seen at operation. In appendicectomy it has been shown (Leigh, 1974a) that the isolation of *B. fragilis* from the appendix fossa is associated with a high incidence of wound infection, and that the administration of effective antibiotic therapy early in the postoperative period can reduce this incidence. Secondly, it is necessary to protect anaerobic bacteria which are highly oxygen-sensitive, and the specimen must be collected from deep in the wound and placed into a transport medium, either Stuart's or Robertson's meat broth, which provides an anaerobic environment. Many operations are performed outside the normal laboratory working hours and immediate examination and culture of the specimen are not possible.

In the laboratory it is always necessary to use selective media to isolate anaerobic bacteria, as it is time consuming and difficult to identify these bacteria amongst large numbers of aerobic organisms which may grow well even under anaerobic conditions. The increase in the isolation rate of *B. fragilis* when these precautions are taken is startlingly high (*Table IV*) and has confirmed the report of other workers (Hoffmann and Gierhake, 1969).

The incidence of wound infection following intestinal surgery is high; in the past it has been accepted as a natural sequel to the opening of the bowel and subsequent contamination of the peritoneal cavity and wound area. In the High Wycombe area in 1973, 15 per cent of patients undergoing major intestinal surgery developed a wound infection, and in 60 per cent *B. fragilis* was the causative organism either alone or in association with other bacteria. It is possible by bacteriological examination of the peritoneal cavity at the time of operation, especially in patients with perforation of the intestine where the incidence of wound infection is high, to diagnose the likely bacterial pathogens and to prescribe antibiotic treatment early in the postoperative period and prevent the subsequent wound infection. This procedure requires close cooperation between the surgeons and the laboratory, but it would be of great benefit to the patients in whom a wound infection may greatly delay their discharge from hospital.

In view of the high frequency of isolation of bacteroides from wound infections following intestinal surgery blind chemotherapy must include an antibiotic such as lincomycin which is effective against these organisms.

Acknowledgements

I would like to thank Mrs E. Norman, Control of Infection sister, who was responsible for the wound infection survey; the consultant surgeons, Mr P. H. Lord and Mr B. Higgs, for allowing the study of their patients; Mrs K. Simmons for the details of antibiotic susceptibility of the strains of bacteroides; and the technicians of the Microbiology Laboratory.

ETHICON
TRADEMARK
Eyeless needled sutures

QUALITY AND RELIABILITY AT EVERY STAGE

ETHICON* Eyeless Needled Sutures offer three outstanding advantages over traditional eyed needles.

Point 1 Consistent high quality—by precisely controlled manufacture of a complete sterile suture in a single package.

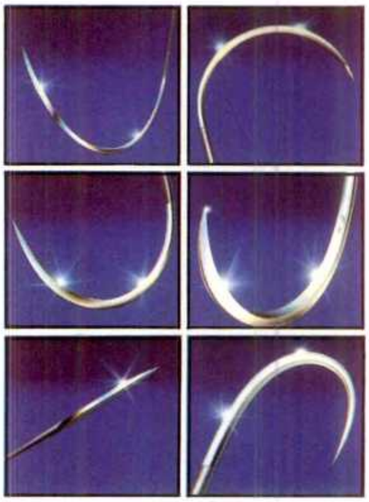
Point 2 A new sharp needle every time.

Point 3 Reduced trauma—with ETHICON eyeless needles there is no large eye and only one strand of material to pass through tissue.

The choice is yours

Most surgeons agree that there is no universal suture. Most probably there never will be. Each patient, each procedure, and each layer of tissue differs from the next. This is why we at ETHICON manufacture such a comprehensive range of eyeless needled sutures.

You can choose from our wide selection of materials, absorbable and non-absorbable, securely attached to a stainless steel needle of your choice. The consistent high quality of ETHICON eyeless needled sutures provides predictable performance. This enables you to concentrate on the most critical aspect of your surgery—the well-being of the patient.



We make
some very important points

Reduce Trauma

ETHICON
Eyeless needled sutures
Widest range. Finest quality

ETHICON Ltd., Bankhead Avenue, Edinburgh EH11 4HE, Scotland

PROLENE* Monofilament polypropylene for security you can count on

When the reliability of a non-absorbable is required in a contaminated or potentially contaminated field many surgeons are now choosing PROLENE suture. Made from polypropylene, a material of relative biological inertness, monofilament PROLENE suture is not degraded by tissue enzymes and is virtually unaffected by the presence of infection.

Security for extended approximation

Where wound healing may be delayed PROLENE suture can be relied on to retain its tensile strength.

Secure knot-holding

PROLENE suture is able to deform and flatten on knotting to give knot security superior to any other monofilament.

Security through reduced risk of suture extrusion and sinus formation

The specially smooth monofilament structure of PROLENE suture and its ability to tolerate infection extremely well can lessen the risk present with a braided suture in a contaminated wound.

Indications: PROLENE Polypropylene suture may be used wherever a non-absorbable surgical suture is recommended.

Precautions: Unused PROLENE sutures may not be autoclaved more than three times by the standard autoclaving method without loss of strength. Care should be taken to avoid damaging the surface of the material with surgical instruments.

Pneumatosis cystoides intestinalis with unexplained ascites in Ethiopian patients

EDEMARIAM TSEGA

SUMMARY

Four cases of pneumatosis cystoides intestinalis associated with unexplained ascites in Ethiopian patients are described. The relationship between the two conditions has not previously been reported.

PNEUMATOSIS cystoides intestinalis (PCI) is an uncommon condition characterized by multiple gas-filled thin-walled cysts of the subserosal and submucosal layers of the intestine. It was first described by DuVernoi in 1730 (quoted by McGregor and McKinnon, 1958), the first detailed report was published by Bang (1876) but the first radiological description was provided by Englund and Wahlgren (1935). In a review of 213 cases Koss (1951) reported that the small bowel was affected in 63 per cent and the large bowel in 22 per cent of cases, the former being commonly associated with gastric or duodenal ulcers. PCI almost invariably occurs in patients suffering from other conditions, mainly of gastro-intestinal or pulmonary origin. Reported associated gastro-intestinal lesions include pyloric stenosis, duodenal ulcer, gastric ulcer or carcinoma, regional enteritis, various forms of colitis, tuberculosis and obscure forms of diarrhoea. PCI also occurs in the presence of chronic pulmonary disease (Doub and Shea, 1960; Keyting et al., 1961; Kenney, 1963). Other conditions associated with PCI include acute leukaemia (Jaffe et al., 1972), lymphoproliferative disorders (Mujahad and Evans, 1958; Williams et al., 1963), progressive systemic sclerosis (Gompels, 1969) and malnutrition (Druckmann et al., 1961).

The purpose of this paper is to describe 4 patients with PCI in whom unexplained ascites was found, a relationship not reported previously in the English literature.

Case reports

Case 1: H. H., a 26-year-old merchant, was admitted to hospital for treatment of a crush injury of the right foot. He also gave a 3-year history of intermittent vomiting of undigested foodstuff preceded by uncomfortable abdominal distension, especially after meals. He had anorexia and marked undetermined weight loss. There was no definite epigastric pain, cough, fever, night sweats or history of jaundice or drug intake.

On examination the patient was noted to be emaciated, pale and chronically ill. His blood pressure was 100/70 mm Hg and his pulse was 100/min. The respiratory and cardiovascular systems were normal. The abdomen was distended, with flank dullness and fluid thrill. No intra-abdominal organs could be palpated. Rectal examination was normal.

Red blood cell count was $2 \times 10^6/\text{mm}^3$ and the ESR 120 mm in the first hour. A Mantoux skin test with 2 units of PPD was negative. The urinalysis and blood urea nitrogen were normal. The liver function tests, including bromsulphthalein, were within normal limits. A bone marrow aspirate was normal and negative for acid-fast bacilli. Diagnostic paracentesis yielded clear yellow fluid containing 500 WBC/mm^3 of which 90 per cent were lymphocytes, with a protein content of 3·5 g/l and no growth of *Mycobacterium tuberculosis* after 6 weeks of incubation. A barium meal examination showed enormous dilatation of the stomach which almost filled the abdomen, and from which no barium had passed after 2 hours.

At exploratory laparotomy approximately 1500 ml of straw-coloured, ascitic fluid were removed. The stomach was dilated to almost four times the normal size but there was no evidence of a gastric lesion or duodenal ulcer. However, the first part (4 cm) of the duodenum was found to be very narrow, with a lumen barely sufficient to allow the passage of a lead pencil, but with no thickening or scarring of the wall. The liver, biliary tree, peritoneum, omentum, pancreas and terminal ileum were all normal. The lower jejunum and upper ileum were noted to have multiple subserosal gas-filled cysts, characteristic of PCI. After an operative diagnosis of congenital stenosis of the duodenum in an adult, a Billroth II anastomosis was performed. The narrow duodenum was removed together with the stomach, but no histological report was obtained.

Four months after operation the patient had no ascites or any symptom and he had gained much weight.

Case 2: M. K., a 14-year-old girl, was admitted to hospital with a history of long-standing recurrent abdominal distension which had suddenly become worse 4 months prior to admission. A month before admission she had experienced a stabbing pain in the right upper quadrant of the abdomen, radiating to the right shoulder and aggravated by deep breathing. There was no history of chronic cough, epigastric pain, vomiting, diarrhoea or jaundice.

On physical examination the vital signs, lungs and cardiovascular systems were within normal limits. The abdomen was markedly distended and tympanitic to percussion over the upper quadrants. The liver dullness was decreased. There was flank fullness and dullness; no intra-abdominal organ or mass could be palpated. The presumptive clinical diagnosis at admission was tuberculous peritonitis.

A plain film of the abdomen in the upright and supine positions revealed pneumoperitoneum and cystic gas collections in the right upper quadrant (*Fig.* 1). A chest X-ray showed normal lungs and air under the right diaphragm. A barium meal study showed downward displacement of the stomach and rapid transit of the barium from the stomach to the small intestine. Barium enema examination and sigmoidoscopy were unrevealing. Haematological and biochemical tests, including liver function tests, demonstrated normal findings. A diagnostic paracentesis revealed straw-coloured fluid with a specific gravity of 1010, protein of 1·64 g per cent, total WBC of 500/mm^3 (69 per cent lymphocytes, 29 per cent neutrophils and 2 per cent oesinophils) and a negative reaction to Gram and Ziehl–Neelsen stains.

At an exploratory laparotomy the presence of air in the intra-abdominal cavity was apparent. Multiple air-filled subserosal cysts were seen from the lower part of the jejunum down to the terminal ileum. About 1500 ml of straw-coloured ascitic fluid were removed. The liver, spleen, pancreas, stomach and duodenum were normal. Biopsies were taken from the omentum, the serosal layer of the small intestine and lymph nodes adjacent to the mesentery. The cysts were described as empty sacs lined with flattened endothelial cells compatible with PCI. No other abnormality was seen.

Fig. 1. *Case* 2. *a*. Pneumoperitoneum and cystic gas collections in the right upper quadrant of the abdomen. *b*. Magnified right upper quadrant.

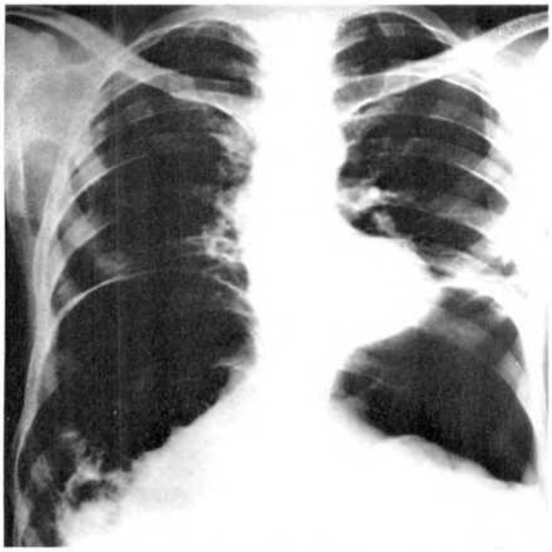

Fig. 2. *Case* 4: Chest X-ray showing pneumoperitoneum.

Follow-up 3 months after operation revealed recurrence of symptoms but without ascites. There was again air under the right diaphragm. A repeat barium meal with fluoroscopy showed retention of contrast medium in the stomach for 24 hours, and there were cystic structures which changed in size with respiration and appeared about to rupture at any moment. A diagnosis of recurrent pneumoperitoneum from ruptured PCI was made.

Case 3: A. T., an 18-year-old man, had had an abrupt attack of weakness and giddiness, followed by massive haematemesis some 6 years prior to admission. Soon after this episode he had begun to experience cramp-like and burning epigastric pain, which continued throughout the 6 years, with a certain degree of rhythmicity and periodicity, often occurring 2 hours after meals and waking him up at 1 or 2 a.m. For the past 2–3 years, he had had postprandial distension, often relieved by either spontaneous or self-induced vomiting. The vomitus had sometimes contained food material ingested 24 hours previously.

Physical examination revealed a thin and undernourished man with flank fullness, shifting dullness and succussion splash several hours after his last meal. There was no other finding.

A barium meal study showed an enlarged and hypotonic stomach with flattened mucosa and with 50 per cent of the barium still present 27 hours later. Haematological and biochemical tests, including liver function tests, revealed normal findings. The clinical impression was benign pyloric obstruction.

At laparotomy 2000 ml of clear ascitic fluid were removed. Extensive gas-filled subserosal cysts were noted extending from the middle of the jejunum to the terminal ileum and a few were seen on the mesentery; a biopsy confirmed the operative impression of PCI. The pylorus was said to be normal by the surgeon. There was no other abnormality.

Six weeks after operation the patient began to complain again of abdominal distension and vomiting. There was no evidence of ascites at this time. A repeat barium meal examination was again suggestive of pyloric obstruction. Gastroscopy revealed a large distensible stomach, flattened mucosa and prominent veins in the antrum. There was no ulcer but the pyloric region revealed a tear-drop type deformity. A second exploratory laparotomy was suggested but the patient refused and discharged himself from hospital.

Case 4: T. W. T., a 42-year-old man, was admitted to hospital with burning epigastric pain and recurrent vomiting after meals. He had weighed 65 kg at one time but was only 39 kg at the time of admission.

On physical examination the patient appeared emaciated, pale, dehydrated and chronically ill, with a blood pressure of 90/70 mm Hg. The respiratory and cardiovascular systems were normal. The abdomen was moderately distended with flank fullness and shifting dullness. There was a succussion splash in the epigastrium several hours after the last meal. The rest of the physical examination was unrevealing.

A chest X-ray demonstrated air under the right diaphragm (*Fig*. 2) and a barium meal film showed a huge stomach with prolonged retention of barium and displacement of the intestine and the colon downwards. The gastric aspirate after an overnight fast was 1400 ml. The haematocrit was 36 per cent and the stool showed occult blood (+ + +). The ESR was 60 mm in the first hour. The serum blood urea nitrogen was 102 mg per cent at the time of admission but decreased to 32 mg per cent after rehydration. The liver function tests were normal.

At laparotomy pneumoperitoneum was evident. More than 3 litres of straw-coloured ascitic fluid were removed from the peritoneal cavity. There were multiple grape-like clusters of gas-filled cysts of varying size studding the subserosal surface of almost the entire small bowel. A complete pyloric stenosis was found and treated with gastrojejunostomy. No other abnormality was detected. The patient did well postoperatively, and has not returned for follow-up since his discharge.

Discussion

Although PCI is said to be rare, more than 300 cases have been reported. It seems that the condition is more common than was previously thought (Elliott and Elliott, 1963; Smith and Welter, 1967). It is often diagnosed at operation or at autopsy but seldom clinically or radiologically. The disease occurs about three times more frequently in males than females (Koss, 1952). The majority of cases are within the age group of 20–50 years. However, there are isolated reports of infants and children who were found to have PCI with or without associated intestinal conditions (Stiennon, 1951; McGregor and McKinnon 1958; Swerdlow, 1964; Smith and Welter, 1967).

The clinical features of PCI include constipation, flatulence, distension, vomiting, vague abdominal pain, diarrhoea and occasionally frank bleeding. Often, most of these symptoms resolve spontaneously. In some cases the associated conditions mask the clinical picture. Intestinal obstruction, pneumoperitoneum, volvulus (Jones, 1948), perforation and prolapse of cysts through the anus (Wyatt, 1972) may rarely occur as complications. Intestinal obstruction results from bulging submucosal cysts (common in children), while pressure exerted by cysts on veins may cause occlusion and subsequent bowel infarction, perforation and peritonitis.

Many cases of PCI remain asymptomatic and are best managed conservatively. Complications such as obstruction, volvulus or adhesion, however, require surgical intervention. Most cases resolve after surgical treatment of the associated or underlying condition, e.g. pyloric stenosis.

One striking feature common to all of the subjects described here is the significant amount of ascites which did not recur after removal at laparotomy and for which no apparent cause could be found. Liver biopsies were not done but the liver function tests and the gross appearances of the livers at surgery were normal in all the cases. Ascites is not a feature of duodenal ulcer or obstruction. There was no apparent cardiac, renal or gastro-intestinal cause. Tuberculous peritonitis was excluded in *Cases* 1 and 2. Surgical exploration has excluded the possibility of the extra-hepatic portal hypertension that may be caused by chronic pancreatitis (Longstreth et al., 1971) or portal vein obstruction. The aetiology of the ascites therefore remains unexplained.

A second interesting finding was pneumoperitoneum, which is a rare complication of PCI (*Cases* 2 and 4). This is usually the result of a spontaneous rupture of subserosal cysts. Silent pneumoperitoneum, sometimes massive, long-standing and recurrent, associated with PCI and without peritonitis has been reported (Druckmann et al., 1961; Elliott and Elliott, 1963). *Case* 2 is a good example of this.

The number of conditions described as being associated with PCI continues to increase but the exact mechanism of cyst formation remains poorly understood. Of several theories proposed, two are generally accepted, viz. mechanical and pulmonary. The mechanical theory maintains that gas from the lumen of the intestine gains access to the tissues through the epithelial wall. This seems likely in duodenal and gastric ulcer, gastric carcinoma, regional enteritis, colitis, neoplastic infiltration of the bowel, following colostomy (Hall, 1971) and trauma secondary to sigmoidoscopy (Marshak et al., 1956). Also, the high percentage of hydrogen in the gas content of the cysts (nitrogen 72·5 per cent, hydrogen 10·1 per cent, oxygen 7·0 per cent, carbon dioxide 1·7 per cent, etc., measured by Hughes et al., 1966) suggests that gas diffuses into the cysts from the bowel, probably under pressure. However, the absence of PCI in most bowel diseases that give rise to mucosal damage and its occurrence without intestinal disease suggest that the mechanical theory does not account for all cases of PCI. The pulmonary theory advocates that ruptured alveoli lead to pneumomediastinum from which air travels along the sheaths of the pulmonary arteries which are in continuity with the fascial sheath of the aorta and its branches and eventually to the walls of the intestine (Doub and Shea, 1960; Keyting et al., 1961; Elliott and Elliott, 1963). Plachta and Speer (1961) and Keyting et al. (1961) have shown experimentally that air will track along the aorta from the mediastinum, and that injection of air into the tissue surrounding the root of the inferior mesenteric artery results in colonic lesions similar to human PCI. However, not all cases of pneumomediastinum give rise to PCI and it is a rare finding among patients with chronic obstructive lung disease. Neither theory accounts for the PCI described either in cases with malnutrition (Druckmann et al., 1961; Jaffe et al., 1972) or in cases without other known disease (Swerdlow, 1964). It would be interesting to know the actual incidence of PCI in the tropics where the prevalence of malnutrition and intestinal parasites is very high.

A striking feature common to 3 of the 4 cases presented here was gross gastric dilatation. *Case* 1 was found to have an organic cause which was surgically corrected and no further trouble occurred. Unfortunately, *Case* 4 did not return for follow-up. In *Case* 2, although the first barium meal showed rapid gastric emptying, a repeat barium study at the time of recurrence of her symptoms revealed significant stasis in the stomach. It is difficult to explain this apparent association between gastric dilatation and PCI, and none of the suggested theories explains the formation of gross ascites in each of the 4 cases. Therefore, the cause of PCI and its relationship to other conditions, including ascites, require further studies.

Acknowledgements

I am grateful to Dr D. Obradovic of St Paul's Hospital and to Drs H. Friedrichs and Adugna Makonnen of Haile Sellassie I Hospital for their surgical assistance.

I thank Dr F. T. Lester of Haile Sellassie I Hospital for permission to report *Cases* 1 and 4. I am indebted to Mr Zewdu Kebede of the Department of Audiovisual Aid, Haile Sellassie I University, for the photographs.

Caecal rupture due to colonic ileus

EUGENE D. GIERSON, F. KRISTIAN STORM, WILLIAM SHAW AND SUSAN K. COYNE*

SUMMARY

Caecal rupture due to colonic ileus is rare and has a mortality rate of 43 per cent. Three new cases are presented and the 18 previously reported cases are reviewed. The disease has always occurred in association with another illness, has usually afflicted patients over the age of 55 and has only resulted when the caecum was at least 9 cm in diameter. The technique of 'blow-hole' caecostomy, a method for decompressing the distended caecum, is described.

CAECAL rupture due to colonic ileus is an unusual complication of pseudo-obstruction of the colon (Ogilvie's syndrome). It is often fatal and is sufficiently rare that we could find only 18 cases in the literature. Low and Fairly reported the first case in 1934, but they failed to recognize the syndrome, probably because ileus of the colon was unknown until Ogilvie's paper in 1948. In 1958 Robertson et al. (unaware of the article by Low and Fairly) claimed the first report, and in 1973 Wojtalik et al. collected 12 cases from the literature and added 3 of their own.

The purpose of our paper is to report 3 cases of caecal rupture due to colonic ileus and to describe the technique of 'blow-hole' caecostomy.

Case reports

Case 1: A 69-year-old man with a long history of peptic ulcer disease was admitted to Sepulveda Veterans Administration Hospital with a diagnosis of perforated duodenal ulcer of 20 hours' duration. The perforation was oversewn shortly after admission. One week later a small leak from the duodenum was treated by coeliotomy and drainage. The patient's postoperative course was complicated by pneumonia, upper gastro-intestinal bleeding, candidaemia associated with hyperalimentation and acute renal failure. Six weeks after the initial operation he developed right lower quadrant abdominal pain and tenderness. Abdominal X-rays showed a dilated caecum, 14 cm in diameter. Gastrografin enema showed no obstruction and no leak. However, 5 days later an X-ray revealed free air in the abdomen with decompression of the caecum. At operation a caecal perforation and diffuse peritonitis were found. Tube caecostomy was performed, using a mushroom catheter, size 26 French. Postoperatively, caecostomy drainage was poor, and 1 week later coeliotomy was done to replace the caecostomy tube and to drain a subphrenic abscess. The patient developed renal failure, pneumonia and hyperbilirubinaemia. Faecal drainage around the caecostomy tube caused peritonitis and sepsis. The patient died of sepsis 20 days after the caecum had perforated.

Case 2: A 59-year-old male was admitted to UCLA Hospital because of weakness and dyspnoea for 2 months. Chest X-ray films revealed an abscess cavity in the left lung and pulmonary emphysema. Incision and drainage of the pulmonary abscess were performed on the day following admission. Postoperatively the patient did poorly. His course was complicated by sepsis, respiratory deterioration, leucopenia and abdominal distension which slowly progressed. On the sixteenth postoperative day abdominal X-ray showed the caecum to be 'markedly distended'. An exploratory coeliotomy revealed two large caecal perforations and no obstruction of the colon. A right colectomy with ileostomy and mucous fistula was done. Postoperatively the patient had sepsis and he died on the day after operation.

Case 3: A 76-year-old female had been asymptomatic for 1 year following a transverse colostomy for diverticulitis. She was admitted to UCLA Hospital because of pain for 2 days in the right lower quadrant of the abdomen. Abdominal distension was present, bowel sounds were active and the right lower quadrant was tender. X-ray films revealed an ileus pattern with a dilated caecum. After 20 hours of observation a barium enema X-ray study was done. It showed extravasation from the caecum into the free peritoneal cavity and no evidence of obstruction. Coeliotomy revealed perforation of an ulcerated necrotic area of the caecum with barium peritonitis. Right colectomy with primary ileocolostomy was performed. Postoperatively, the patient had sepsis and she died on the sixth postoperative day. At autopsy the absence of colonic obstruction was confirmed.

Discussion

Table I summarizes the cases reported in the literature as well as our cases. There are a total of 21 cases, and most of the patients were over 55 years. In each case there was an associated major illness or trauma, or the patient had had recent surgery. Apart from the fact that there was an associated disease of some sort, no consistent pattern was discernible. Diagnosis was established when symptoms and signs of an abdominal catastrophe led to coeliotomy. Preoperative X-rays were not reliable for determining perforation; free intraperitoneal air was absent in one-half of the cases and barium enema studies showed a similar rate of error. The caecal diameter was always 9 cm or larger, ranging from 9 to 20 cm. The operation most frequently performed was tube caecostomy, with a 20 per cent mortality. Overall, the mortality rate was 43 per cent and hospital stay averaged 6·8 weeks for surviving patients. Moreover, in excess of 60 per cent of patients suffered major postoperative complications, including evisceration, stress ulcer, peritonitis and abdominal abscesses. Thus, even for survivors this was a disastrous illness.

How can the caecum perforate in the absence of distal obstruction? We propose the following sequence. A disease process not involving the bowel results in an imbalance of sympathetic and parasympathetic activity (Ogilvie, 1948; Dunlop, 1949; MacFarlane and Kay, 1949; Wanebo et al., 1971). Colonic peristalsis ceases.

* Presumed to be tube caecostomy though not stated in report.

Gas accumulates due to swallowed air, bacterial by-products and gas from the bloodstream, entering the gut lumen by diffusion (Wangensteen, 1955). Normally, gas is carried away by the motility of the colon and by bloodstream absorption, but in the face of an ileus, distension progresses and is most severe in the caecum because of its weak wall. Increasing distension impedes blood flow, causing necrosis of the caecal wall and perforation. An incompetent ileocaecal valve does not guarantee against caecal rupture (Eckman et al., 1958; Robertson et al., 1958).

With a mortality rate of 43 per cent, prevention of caecal perforation is important. In turn, prevention requires the ability to predict in advance which caecum will rupture. This seems to be related to caecal diameter, perforation having occurred only if the diameter had reached at least 9 cm. Moreover, the normal caecum is less than 9 cm (Davis and Lowman, 1957). We therefore propose the 'rule-of-nine': a caecum distended to 9 cm is in danger of perforating. This circumstance requires careful therapy. We think it safest to perform 'blow-hole' caecostomy (described below), but if non-operative therapy is elected the patient should be observed closely.

The operation to create a 'blow-hole' caecostomy is sufficiently simple and safe that it can be done using local anaesthesia. After surgery one can be confident that the caecum will remain decompressed, and the problems of a tube caecostomy are avoided. Such problems include occlusion of the catheter by faeces, spillage of faeces into the abdominal cavity and postoperative recurrent caecal rupture. Tube caecostomy has failed in up to 50 per cent of cases and has been condemned by many (Gregg and Dixon, 1941; Hendricks and Griffin, 1947; Michel and McCafferty, 1948; Albers and Smith, 1952; Hunt, 1954; Rack and Clement, 1954; Maynard and Turell, 1955). Moreover, inadequate function of the tube can be fatal (Jackson and Baird, 1967; Hopkins, 1969; Balslev et al., 1970; Norton et al., 1974). Although many reports have been unfavourable, Wanebo et al. (1971) reported good results in 4 patients. When complications of tube caecostomy do occur they are so disastrous that we recommend avoiding the tube entirely and using the 'blow-hole' technique instead.

Technique of 'blow-hole' caecostomy (*Fig.* 1)

Local 0·25 per cent lidocaine (Xylocaine) with epinephrine (Gierson, 1972) or light general anaesthesia is used. A 5-cm transverse incision is made 5 cm cephalad to the right anterior superior iliac spine, lateral to the rectus muscle. The internal oblique, external oblique and the transversalis muscles may be split or cut. It is important to remain lateral to the rectus muscle to ensure that the caecum is encountered and not the small bowel. The distended caecum will 'pop' into the wound and is identified by the presence of taeniae. It is desirable to have a portion of the caecum protrude above the skin, as this facilitates placement of a colostomy bag.

The seromuscular layers of the caecum are sutured to the external or internal oblique muscles, care being taken to include the aponeurosis of these muscles in each suture; 3/0 silk sutures, swaged on to a gastrointestinal needle, are used. Care is taken not to penetrate the mucosa of the bowel. These interrupted sutures are placed circumferentially, and closely spaced to ensure a watertight seal. If there is doubt that a watertight seal has been achieved, a second layer of sutures is placed, joining the caecal wall to the subcutaneous fat (Turnbull et al., 1971).

The caecum is incised with a scalpel through the taenia or through a lateral-inferior area. Large quantities of gas and faeces will spill out. A lateral-inferior incision facilitates gravity drainage into the subsequently placed colostomy bag. Cautery should not be used, as explosion may result (Barrkman, 1965; Ragins et al., 1974). Bleeding of the cut edges of the caecostomy is controlled by clamp and silk ligature. The skin is not closed.

Epidermoid cysts, polyposis coli and Gardner's syndrome

BARBARA LEPPARD AND H. J. R. BUSSEY*

SUMMARY

One hundred and ninety-six members of 15 families with Gardner's syndrome were investigated to determine the type of skin cyst that is part of this syndrome. These were shown to be epidermoid cysts and not pilar cysts or steatocystoma multiplex. They were solitary or multiple and seldom large and disfiguring. The skin cysts often occurred before the intestinal polyps were detectable. The presence of epidermoid cysts in children should be an indication for sigmoidoscopy when the child reaches the age of 14 years, and at 3-yearly intervals thereafter up to the age of 30 years, whether or not there is a family history of polyposis coli.

At present it is not possible to say if Gardner's syndrome is the same as, or different from, familial polyposis. Until all patients with colonic polyps have a full clinical examination, looking for skin cysts and osteomas, X-rays of the skull and long bones to detect osteomas and dental X-rays for abnormalities of the teeth this question will remain unanswered.

FAMILIAL polyposis coli is an inherited condition in which many hundreds or even thousands of adenomatous polyps develop in the colon and rectum. It frequently manifests itself at an early age (20–30 years) and is associated with a high incidence of intestinal carcinoma. The familial nature of the disease was first noted by Cripps (1882), and its inheritance as a Mendelian autosomal dominant trait was established by 1930 (Dukes, 1930).

During the years 1950–3, Gardner and his co-workers (Gardner and Stephens, 1950; Gardner, 1951; Gardner and Plenk, 1952; Gardner and Richards, 1953) published a series of papers describing a family in which several members were affected with a triad of lesions, that is, (1) multiple adenomatous polyposis of the large intestine, (2) multiple osteomas of the skull and mandible and (3) multiple epidermoid cysts and fibromas of the skin. This syndrome, later named after Gardner, has been extended by the addition of other features such as dental abnormalities, desmoid tumours of the abdominal wall and abdomen and malignant disease of the thyroid gland and periampullary region of the duodenum. Some of these extracolonic lesions may be present for a long time before the intestinal polyps give rise to symptoms. Apart from the large bowel adenomas which are always present, the most constant component of Gardner's syndrome on clinical examination is the occurrence of epidermoid cysts.

An investigation into the nature, incidence and mode of inheritance of the skin cysts of Gardner's syndrome was carried out as part of a large survey of benign familial skin tumours.

Present study

Ascertainment

The St Mark's Hospital Polyposis Register, which was established in 1925 by Dr Cuthbert Dukes, now contains details of 200 families with at least one member affected with polyposis coli. One hundred and ninety-six members of 15 of these families were investigated. Some individuals were seen in the outpatients' department or in the wards of St Mark's Hospital and others were visited in their homes. Letters were sent to those who lived too far away to be visited, and hospital notes and histopathological specimens were obtained when possible and, in particular, for any patient who had died before the study began. Sixty patients were seen and examined by one of us (B. L.) either at the hospital or at home. Information from hospital notes was available on 82 patients, 25 replied to letters and information on the other 29 was obtained from other members of their families.

Method of investigation

When the patients were first seen pedigree details were recorded, a full medical history was taken and a complete clinical examination was carried out. If the patient was over 14 years of age sigmoidoscopy and biopsy of rectal polyps, if these were present, were done and the extent of the polyposis delineated by barium enema examination. When a patient was discovered to have polyposis coli, as many of his relatives as possible were then seen and examined.

Results

Intestinal polyps

Of the 196 patients for whom information was available, there were 108 who were likely to be affected and 88 who were definitely unaffected. Of the 108 possibly affected individuals, 74 definitely had polyposis coli, 5 died of carcinoma of the colon or rectum before the age of 40 years and therefore were probably affected, 5 aged between 20 and 30 years had no polyps on sigmoidoscopy and were probably unaffected and 24 under the age of 17 years either showed no polyps on sigmoidoscopy or were too young to have been examined by sigmoidoscopy. The rest of this paper will be confined to a discussion of the 74 definitely affected patients.

---

* St Mark's Hospital, London.
Present address of B. Leppard: St John's Hospital for Diseases of the Skin, London WC2H 7BJ.

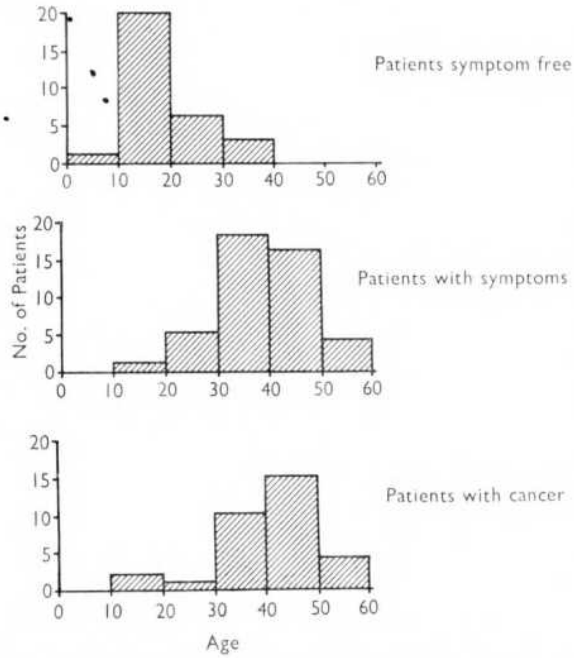

Fig. 1. Age at which polyps were discovered in 74 affected individuals from 15 families.

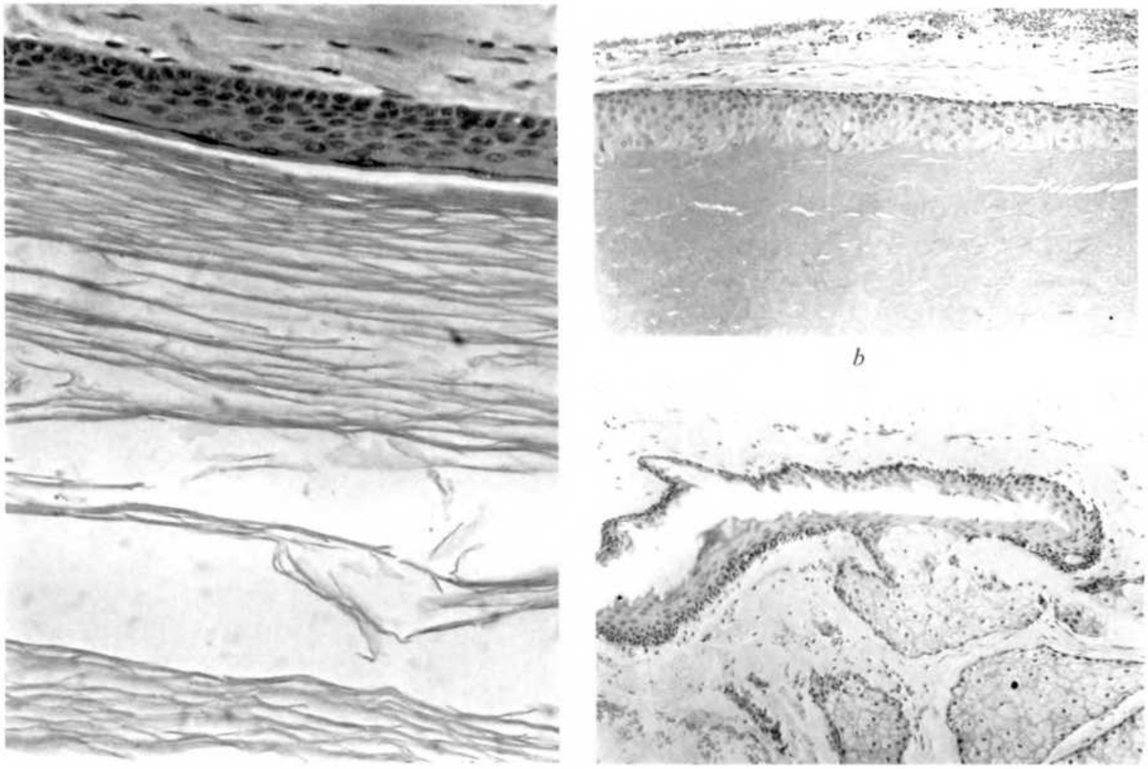
Approximately half of the affected patients (38 cases) had complained of intestinal symptoms such as rectal bleeding, diarrhoea, constipation or abdominal pain. The age of onset of the symptoms varied between 17 and 60 years, with a mean of 40 years. Polyposis was discovered in the other 36 individuals when they were examined because of a positive family history. The age at which the polyps were found in this group varied from 10 to 57 years of age, with an average of 23 years. This difference between the two groups was statistically significant ($P < 0{\cdot}05$ using the *t*-test). Thirty-nine patients were found to have a carcinoma when their colons were removed. From *Fig.* 1 it can be seen that the age of discovery of polyps for those in whom a carcinoma was found at colectomy was very similar to that of those with bowel symptoms, which suggested that the age of onset of symptoms probably corresponded to the age at which malignant change took place in one or more of the polyps.

Skin cysts

Incidence and type of cyst in polyposis patients: Cysts of the skin were found in 39 (53 per cent) of the 74 patients with polyposis. Microscopical examination of 24 cysts from 15 patients all showed the characteristic features of epidermoid cysts (*Fig.* 2*a*). No



a *b* *c*

Fig. 2. Histological features of 'sebaceous cysts'. *a*, Epidermoid cyst. The lining is the same as normal epidermis, with a gradual flattening of cells as they mature, a granular layer and flaky basophilic-staining keratin in the centre. HE. (× 96.) *b*, Pilar cyst. Individual cells become bigger and fatter as they mature and the centre of the cyst is filled with solid eosinophilic-staining keratin. HE. (× 72.) *c*, Steatocystoma multiplex. The lining cells are different from both (*a*) and (*b*). Individual cells break off into the centre of the cyst and sebaceous glands are seen to make up part of the cyst wall. HE. (× 72.)

examples of pilar cysts or steatocystoma multiplex were found.

Number and position of cysts: The number of cysts per patient varied from 1 to 20, the average being 4. Thirteen (33 per cent) of the 39 patients had solitary cysts. Of those with multiple cysts, in only 1 patient were they large and disfiguring. The site of the cysts is shown in *Fig.* 3. The commonest site was the legs, followed by the face, scalp and arms. The trunk was relatively seldom involved.

Age distribution: The age of onset of the cysts was from birth to 35 years, with an average of 13 years. This was statistically significantly earlier than the clinical manifestations of the colonic polyps ($P < 0{\cdot}01$) and confirms previous observations that the cysts might be used as a guide to indicate which members of a family would later develop polyps (Gardner and Richards, 1953; Coli et al., 1970).

In a group of patients with epidermoid cysts, but without Gardner's syndrome, the average age of onset of these cysts was found to be 26 years, with a range from birth to 58 years (Leppard, 1975). Only 2 patients in this group were found to have cysts before the age of 15 years. On the other hand, 13 (18 per cent) of the 74 patients in this study who had polyposis coli had cysts removed in childhood without the diagnosis of Gardner's syndrome being considered.

Table I: ASSOCIATED LESIONS OF GARDNER'S SYNDROME IN 74 PATIENTS

Lesion	Affected individuals	
	No.	%
Epidermoid cysts	39	53
Osteomas	18	24
Abnormal dentition	13	18
Desmoid tumours	5	7
Malignant tumours (other than those of the rectum and colon)	5	7

Association with other lesions of Gardner's syndrome: Details of the 74 polyposis patients who had the various lesions of Gardner's syndrome are given in *Table I.*

Clinical features

The affected individuals in 4 pedigrees will be described (*Fig.* 4). These pedigrees illustrate the chief points seen in the 15 families investigated.

Pedigree A

II.2: I. S., male, aged 43 years. The proband first developed a cyst on the back of his neck at the age of 26 years and a second on his forehead at the age of 30. Four years later he had an osteoma removed from his right great toe. At the age of 37 years he developed diarrhoea and rectal bleeding and was found to have polyposis coli and a carcinoma arising from the largest of the polyps. He was treated by panproctocolectomy and ileostomy.

III.1: G. S., female, aged 20 years. She first developed a cyst on the forehead at the age of 8 years and since then 4 more have appeared on the right temple, left cheek, right calf and over the

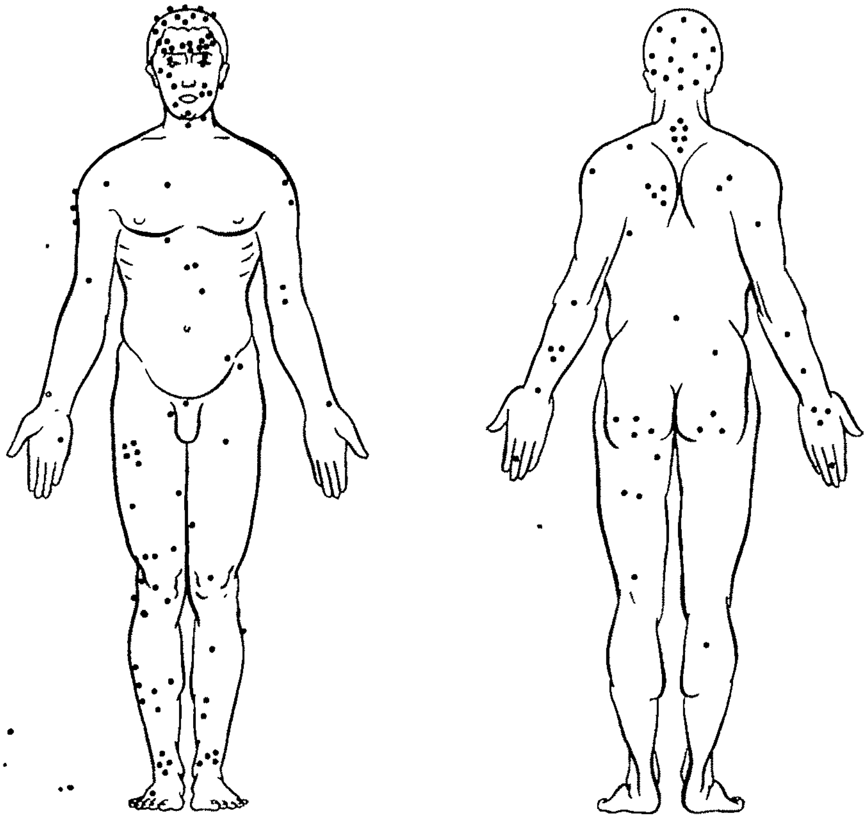


Fig. 3. Site of cysts.

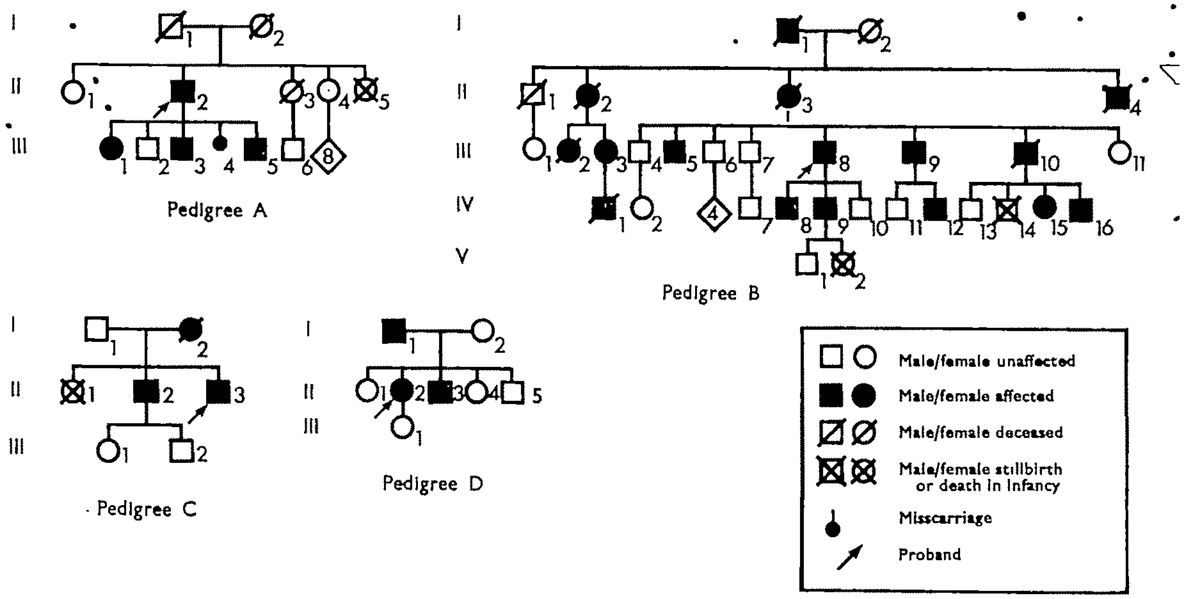

Fig. 4. The 4 pedigrees studied in detail.

right deltoid respectively. Because her father was known to have polyposis coli she was examined by sigmoidoscopy at the age of 13 years and found to have a few polyps. At the age of 17 years she developed rectal bleeding; a colectomy and ileorectal anastomosis were performed a year later. She had no obvious osteomas but she had 2 unerupted teeth in the left upper jaw.

III.2: P. S., male, aged 18 years. He had no cysts on the skin, no obvious osteomas or abnormalities of his teeth and sigmoidoscopy on four occasions was normal. He is regarded at present as unaffected.

III.3: P. S., male, aged 16 years. He first developed a cyst on the scalp at the age of 18 months and a second one on his right ankle at the age of 10 years. Sigmoidoscopy at the age of 13 years showed a few polyps in the rectum and a biopsy of one of them was reported as an adenomatous polyp. He had no osteomas or abnormalities of his teeth.

III.5: M. S., male, aged 14 years. He had 2 cysts, 1 on the left side of his back and 1 on the right thigh, which had been present since early childhood. Sigmoidoscopy in 1974 confirmed that he also had polyposis.

Comment: In this family all the individuals with polyposis coli have skin cysts, in contrast to pedigrees B, C and D.

Pedigree B

III.8: G. P., male, aged 61 years. The proband began to develop cysts at the age of 16 years and has had 4 altogether, 2 on his face, 1 on the left arm and 1 on the right shin. At the age of 18 years he noticed a hard bony lump at the left angle of his jaw and since then 2 other osteomas have appeared on the left side of his scalp. At the age of 41 years he was admitted as an emergency to another hospital where he was found to have polyposis coli and a carcinoma at the rectosigmoid junction. He was transferred to St Mark's Hospital where colectomy and ileorectal anastomosis were performed.

I.1: M. K., male. He died aged 48 years of a carcinoma of the bowel.

II.2: E. D., female. She died aged 49 years of a carcinoma of the bowel.

II.3: E. P., female. She died aged 49 years of a carcinoma of the colon. Several members of the third generation remember her as having a large cyst on the scalp.

II.4: S. K., male. He died aged 49 years of a carcinoma of the colon.

III.2: M. W., female. At the age of 45 years she developed colicky abdominal pain and irregular diarrhoea. Sigmoidoscopy showed multiple polyps in the rectum. A colectomy and ileorectal anastomosis were performed. All the lesions were benign, but she died of a pulmonary embolus 3 days postoperatively.

III.3: H. de L., female, aged 55 years. At the age of 29 years she developed rectal bleeding. Sigmoidoscopy showed large numbers of polyps in the rectum. A colectomy and ileorectal anastomosis were performed and she has remained well since then. She lives in Canada, but in a recent letter she said that she had never had any cysts on the skin or obvious bony lumps.

III.5: J. P., male. At the age of 32 years he was investigated for chronic diarrhoea and found on barium enema examination to have a mass in the midsigmoid region. Laparotomy revealed a carcinoma with malignant glands along the aorta. He died a few months later.

III.9: G. P., male, aged 59 years. He first noticed cysts on the skin at the age of 12 years and he has had 10 on his face, scalp and legs. He was first seen at St Mark's Hospital when aged 38 years because his brother (III.8) had been found to have polyposis. G. P. was also found to have polyps and a colectomy and ileorectal anastomosis were performed. At the age of 57 years he had all his teeth removed because of dental caries, at which time the dentist noticed an osteoma of the mandible.

III.10: V. P., male, aged 53 years. This patient had 8 cysts on the skin which first appeared at the age of 21 years. In his mid-twenties he developed diarrhoea and rectal bleeding and at the age of 29 years he was found to have a carcinoma of the rectum. An abdominoperineal excision of the rectum was performed, leaving the patient with a colostomy. At the age of 46 years he had an episode of subacute intestinal obstruction and rapidly lost 6·4 kg in weight. Investigation showed him to have polyposis coli and two separate carcinomas of the colon. A total colectomy and ileostomy were performed. Three years later he became jaundiced and was found to have a carcinoma of the ampulla of Vater which was removed by pancreaticoduodenectomy. At operation there were several small duodenal polyps which were reported as hamartomas on histological examination. Three years after this third operation he developed widespread metastases and died.

IV.1: D. McL., male. Routine sigmoidoscopy at the age of 15 years showed that this patient had polyps in the rectum. At the age of 17 years he developed raised intracranial pressure and at operation was found to have a medulloblastoma. He died 3 days postoperatively.

IV.8: R. P., male, aged 28 years. He was mentally retarded. Polyposis was discovered by routine sigmoidoscopy at the age of 17 years. He had 1 cyst on his right buttock which appeared at the age of 23 years. He had no osteomas, but at the age of 28 years he still had all his first dentition.

IV.9: C. P., male, aged 26 years. At the age of 15 years he was found to have polyps on sigmoidoscopic examination. He had 1 cyst on his right forearm and 2 osteomas, 1 on the left maxilla and 1 on the scalp.

IV.12: B. P., male, aged 27 years. He developed cysts on the skin, a large lipoma on the back of his neck and an osteoma of the left mandible at the age of 11 years. Polyposis was found at the age of 12 years by sigmoidoscopy.

IV.15: C. S., female, aged 27 years. She first developed an osteoma on the back of the scalp at the age of 11 years, and now has 2 in the occipital region and 1 on her right middle finger. Polyposis was discovered at the age of 19 years and colectomy and ileorectal anastomosis were carried out a year later. Fourteen months after colectomy she developed a large mass in the abdomen and at laparotomy was found to have several desmoids in the mesentery of the small bowel. Because of their large size it was impossible to remove them. She has never had any cysts on the skin.

IV.16: C. P., male, aged 20 years. Polyposis was found at the age of 12 years by sigmoidoscopy. He had no cysts or osteomas visible and no obvious abnormality of his teeth.

Comment: In this family only about half of the affected members had skin cysts. Approximately half also had osteomas, but desmoid tumours were seen in 1 patient (IV.15) and abnormalities of the teeth were only present in 1 patient (IV.8). Two patients had tumours of other organs—a medulloblastoma in IV.1 and a carcinoma of the ampulla of Vater in III.10. One patient (IV.16) had no features of Gardner's syndrome other than the polyposis coli. Some details of this family were first reported by Parks et al. (1970).

Pedigree C

In this family none of the affected members had cysts. The mother (I.2) died at the age of 54 years with a carcinoma of the rectum and polyposis coli. Both her sons (II.2 and II.3) had osteomas. The proband (II.3) had an osteoma of the left mandible which became clinically obvious at the age of 13 years and interfered with his performance on the violin. It was removed surgically and shown histologically to be an osteoma. His brother (II.2) had only 1 small osteoma in the left parietal region, but he has had a Sertoli cell tumour of the left testis. Neither brother had cysts of the skin or obvious dental abnormalities; no desmoid tumours have developed in the 13 years since colectomy. The 2 children of II.2, aged 6 and 3 years respectively, as yet show no evidence of cysts or osteomas.

Pedigree D

In this Negro family only the proband (II.2) had any features additional to the polyposis coli. This patient, a 19-year-old female, developed a large desmoid tumour of the mesentery of the small bowel at the age of 16 years. Two years later she had a recurrent desmoid tumour in the abdominal wall and the diagnosis of polyposis coli was considered. Polyps were found on sigmoidoscopy, and colectomy and ileorectal anastomosis were carried out at the age of 19 years. When this was done 2 further desmoid tumours were present in the anterior abdominal wound. She had no cysts or osteomas on clinical examination and her teeth appeared normal.

Genetic findings

From the 4 pedigrees shown in *Fig.* 4 it can be seen that polyposis coli is inherited as an autosomal dominant trait. Taking all the 15 families and excluding the probands and the affected individuals in the older generations for whom there is only hearsay evidence, we saw 56 affected patients (27 males and 29 females) and 70 unaffected individuals (36 males and 34 females). This gives an approximation to a 1 : 1 ratio both in total numbers of affected to unaffected and in numbers of males to females. All the affected individuals had the intestinal polyps, but the other lesions of Gardner's syndrome were present in varying combinations in different families and in different members of the same family. This was very apparent in pedigree B.

Discussion

Skin cysts in Gardner's syndrome have been referred to as 'sebaceous cysts', 'epidermoid inclusion cysts', 'sebocystomatosis' (steatocystoma multiplex) and 'atheromas'. These terms seem to have been used interchangeably, as if they represented the same condition. However, the 'sebaceous cyst' is not a single entity but any one of three conditions—pilar cysts, epidermoid cysts or steatocystoma multiplex.

Pilar cysts, the common wens, present as solitary or multiple firm intradermal or subcutaneous swellings, usually on the scalp. They have no obvious punctum. Epidermoid cysts may be solitary or multiple, they occur anywhere on the body surface and frequently, but not always, have a visible punctum. Clinically, pilar cysts and epidermoid cysts may be confused, but the site and the presence or absence of a punctum help to differentiate them. Steatocystoma multiplex presents a different clinical picture. Individual lesions are small (0·5–0·8 cm), skin-coloured or yellow or bluish intradermal nodules, which are always multiple. They are situated on the front of the chest or in the axillae and groins. They appear in the late teens or early twenties and then remain static for the rest of the patient's life. Histological examination of the three types of cyst shows them to be quite distinct (*Fig.* 2).

The cysts we found in Gardner's syndrome were epidermoid cysts and not pilar cysts or steatocystoma multiplex. They were either solitary or multiple and most patients had only a small number. Although they could be disfiguring, as they were in one of our patients and in many of the reports in the literature (e.g. Weary et al., 1964), they were often small and not noticed by the patient. In none of our families were they obvious as a family trait. This is in contrast to most of the reports of Gardner's syndrome, which stress very numerous large cysts (Oldfield, 1954; Fader et al., 1962).

The skin cysts can be seen many years before the intestinal polyps, but they do not necessarily occur in all the affected members of a family (contrast pedigrees A and B). Although they may be a guide as to which individuals will later develop polyps, this is not entirely reliable. However, all the patients who had cysts also had, or later developed, polyps.

Eighteen per cent of the patients in this study had cysts removed in childhood without the diagnosis of Gardner's syndrome being considered. This is the usual pattern of events, the diagnosis only being considered when bowel symptoms develop (Duncan et al., 1968). This is shown very well by the three reports of a family from Leeds. In 1937 Ingram and Oldfield first reported this family as having hereditary sebaceous cysts. These were called 'steatocystoma multiplex', but from the clinical description and histological features they were epidermoid cysts. Two brothers and a sister were described who had numerous, large and disfiguring cysts on the face, scalp, trunk and limbs in childhood. Seventeen years later Oldfield (1954) reported the same family, having found, when bowel symptoms developed, that its members had polyposis coli. Two of these patients died (at the age of 32 and 31 years) with carcinoma of the rectosigmoid and rectum respectively. In 1970 one member of the same family was included in a study by McAdam and Goligher (*Case* 3) because, in addition to the cysts and polyposis coli, he developed multiple desmoid tumours. This family therefore, probably fits best into the diagnosis of Gardner's syndrome.

Epidermoid cysts are very uncommon in children (Leppard, 1975), and those who develop them before puberty should probably have a sigmoidoscopic examination every 3 years from the age of 14 years onwards, whether or not there is a family history of polyposis coli. Individuals of any age who present with pilar cysts or steatocystoma multiplex do not need routine sigmoidoscopy.

There is considerable difficulty in defining Gardner's syndrome. The original description by Gardner (1951) included patients with polyposis coli and multiple hard and soft tissue tumours. In 1962 and 1969 he modified this somewhat to include dental abnormalities as well. Thomas et al. (1968) accepted patients with the original triad of lesions with or without a positive family history or a patient with one or more of these manifestations in whose family there were members with the complete triad. Possibly the term should be applied to families rather than individuals. The mode of inheritance as an autosomal dominant trait is not in dispute, but whether one or several genes are involved is unknown. McKusick (1962) believed that Gardner's syndrome is determined by a single gene which is distinct from that for polyposis coli alone. On the other hand, Smith (1968) believed that Gardner's syndrome is the complete manifestation of a spectrum of pathological changes which could affect in variable numbers and combinations any patient who had multiple polyposis. He maintained that patients with polyposis coli who have these extra features do not form a special subgroup and that one gene mutation only is necessary to explain all the lesions.

Families C and D include individuals diagnosed as suffering from familial polyposis, some of whom also had additional lesions. Two brothers in family C had osteomas and 1 member of family D had desmoid tumours. None of these patients had epidermoid cysts and no member of these 2 families had the complete triad. The more intensive the search for extracolonic lesions in patients with polyposis coli, the greater the number found to be present. Only when all such patients have a full clinical examination for surface tumours, X-rays of the skull and long bones to detect osteomas and X-rays of the jaws to exclude dental abnormalities will it be possible to determine the incidence of the various lesions. It is possible that such complete investigations will increase the incidence rate of extracolonic lesions associated with polyposis coli but will not alter the variable expression of these lesions recorded so far. They should, however, resolve the problem of whether or not familial polyposis and Gardner's syndrome are genetically different diseases.

Acknowledgements

We thank the consultant surgeons at St Mark's Hospital for their permission to examine and visit their patients, Dr B. Morson for help with the histological studies and Dr R. S. Wells for his help in the preparation of this manuscript.

Chronic hydradenitis suppurativa: a report of 9 cases

HUMPHREY PIGOTT AND HAROLD ELLIS*

SUMMARY

This paper describes the treatment of 9 patients suffering from hydradenitis suppurativa all of whom were treated by surgical excision. The aetiology, diagnosis and treatment by surgical excision are discussed.

HYDRADENITIS suppurativa is an ill-recognized chronic inflammation of the apocrine glands of the skin. These glands differ in structure, function and distribution from the more numerous tubular eccrine sweat glands and compound areolar sebaceous glands. Failure to diagnose this chronic disabling condition often results in delay of effective treatment.

This paper describes 9 patients suffering from the condition, 8 of whom were initially incorrectly diagnosed with subsequent delay in reaching surgical cure.

Case reports

Case 1: S. S., a hairdresser aged 22 years, complained of persistent discharging axillary sinuses from the age of 19, for which she had been treated with repeated unsuccessful courses of antibiotics and local radiotherapy. On examination there was active hydradenitis suppurativa in the right axilla. In November 1969 local excision with primary suture was performed, with no subsequent abscess formation.

Case 2: C. T., an ex-SRN aged 39 years, had suffered from persistent discharging axillary sinuses of the left axilla for 3 years, and had been treated with repeated unsuccessful courses of antibiotics. On examination active hydradenitis suppurativa was present. Culture of the pus showed coagulase negative staphylococci. In November 1970 local excision with primary suture of the left axilla was performed. Wound infection delayed healing for 2 months. In September 1971 the patient was readmitted at her own request for excision of active hydradenitis suppurativa of the other axilla. The wound healed well, and no further suppuration of either axilla has occurred.

Case 3: S. L., a pupil nurse aged 19 years, had had discharging abscesses in the axillary skin on both sides from the age of 11. On examination chronic hydradenitis suppurativa was present. In June 1972 the left axillary skin was excised, and in September 1972 the right axillary skin was excised. In January 1973, August 1973 and March 1974 further bilateral excisions of small recurrent sinuses were performed. Typical hydradenitis suppurativa was seen on microscopic examination.

Case 4: K. O'C., a housewife aged 39 years, had had chronic axillary sinuses for 1 year. In November 1973 bilateral axillary skin excision with primary suture was performed. She remains well.

Case 5: S. A., a housewife aged 24 years, had had chronic axillary sinuses for 4 years. Unsuccessful repeated antibiotic courses had been given. On examination typical chronic hydradenitis suppurativa was present (*Fig.* 1). In July 1974 bilateral excision of the axillary skin was performed.

Case 6: M. M., a cleaner aged 44 years, had suffered from severe acne as an adolescent, with recurrent discharging sinuses of the axillae from the age of 18, for which she had received multiple incision and drainage procedures. In 1965 excision of the axillary skin on the right side was performed with split-skin grafting of the skin defect. A similar procedure was performed on the left side in 1967. No further abscesses occurred in either axilla. In January 1973 a persistent discharge from the right groin developed which was treated with local excision and primary suture in February 1974. A recurrent area of hydradenitis suppurativa was excised in May 1974.

Case 7: P. R., a housewife aged 26 years, presented with a 1-year history of intermittent discharging sinuses of both groins, but no axillary symptoms. In June 1972 local excision of the groin skin was performed with primary skin suture. Low grade wound infection delayed healing for 6 weeks. No subsequent sinus formation has occurred. Hydradenitis suppurativa was confirmed on microscopic examination.

Case 8: D. W., a lorry driver aged 50 years, was first seen in 1971 with a 2-month history of inguinoscrotal abscess formation. The initial diagnosis was of an anterior pilonidal sinus, and was treated by incision and drainage. He admitted to frequent recurrent axillary boils for many years. From 1971 to 1972 there was persistent perianal sinus discharge. On examination indurated sinus formation was found at the base of the scrotum. In May 1972 local excision and primary suture was performed with no subsequent sinus formation.

Case 9: J. B., a housewife aged 38 years, was referred to the Surgical Outpatients' Department by the Westminster Hospital Casualty Department with a diagnosis of hydradenitis suppurativa (*Fig.* 2). The disease had been present for 1 month, localized to the right axilla. She was treated by excision and primary suture in August 1974.

Discussion

The first description of hydradenitis suppurativa is attributed by Conway et al. (1952) to Velpeau in 1839. The existence of the apocrine glands was shown by Robin in 1845. These glands are gathered into small groups and discharge into the cavity of the hair sheath (*Fig.* 3). They represent a scent gland of sexual function in certain lower animals and are influenced by the endocrine changes of the menstrual cycle. Greeley (1951) suggested that a similar pubertal activation of the glands occurs in man, where they are found in the axilla, areola of the breast, subumbilical and inguinal areas, as well as in the perianal region, where they are known as the glands of Gay (Williams, 1953). Hydradenitis suppurativa only occurs in the areas where there are apocrine glands.

Most of the reports of hydradenitis suppurativa emphasize the delay in reaching the diagnosis (Conway et al., 1952). This feature is supported by all our cases except one (*Case* 9). Most of our patients had received repeated courses of systemic antibiotics, local applications and the use of bactericidal soaps without benefit. Brunsting (1939) mentioned how the diagnosis is often obscured under many miscellaneous names such as abscess, furunculosis, pyoderma, chronic undermining burrowing ulcer of the skin and non-specific granuloma. The chronic nature of the disease with extensive

and persistent sinuses in the subcuticular fat layer is, however, characteristic, and, once recognized, easy enough to diagnose almost at a glance.

Williams (1953) has drawn attention to the scarcity of reports in the English journals, but the account of 388 patients collected over an 8-year period at the Mayo Clinic suggests that the disease may be more common than is appreciated (Jackman and McQuarrie, 1949). The condition is most often found in the third and fourth decades of life (Masson, 1969). The sex incidence appears to be equal for the common axillary lesion, but men are more liable to the perianal disease.

The initial lesion is a superficial abscess which progresses to the characteristic chronic indolent inflammatory disease of the skin with indurated scar tissue burrowing into the subcutaneous fat. Microscopic examination shows the initial infection to be confined to the apocrine glands, with subsequent involvement of the adjacent eccrine glands. The infection spreads through the subcutis via distended lymphatic channels.

In the florid case there is extensive local destruction with chronic inflammatory cells and dense fibrous tissue formation (*Fig.* 4). Large pale-staining giant cells can be seen, which may represent the remnants of the epithelial cells which line the apocrine gland (Brunsting, 1939).

Bacteriological culture usually shows a coagulase positive or negative staphylococcal infection. In long standing cases the variety of bacteria is greater (Masson, 1969).

Surgery offers the only chance of control of the well-established condition, athough it may have to be repeated several times to remove local recrudescences, as shown by *Case* 3. Chronic hydradenitis suppurativa cannot effectively be treated by systemic or local antibiotics and bactericidal solutions are equally inappropriate.

Excision with primary suture is simple and effective for small areas such as the axilla (*Case* 5). This method is also suitable for the groin, as is demonstrated by *Case* 7, although recurrent areas may require re-excision. The chronic inflammatory nature of the condition leads to occasional wound breakdown following primary suture, but this can be minimized with the application of local antibiotic powder such as ampicillin 1 g prior to wound closure. Large areas of axillary skin excision may give rise to unsightly contractures which can be avoided by split-skin grafting or rotational skin flaps (Harrison, 1964). Primary suture with Z-plasty has been advocated for such axillary excisions (Greeley, 1950).

Perianal hydradenitis occurs more commonly in men. *Case* 8 illustrated the frequent occurrence of the condition in lorry drivers which has been previously described (Adams and Harsten, 1972). Small areas can be treated by excision and suture, but when larger areas are found, more extensive excision with skin grafting may be required and preceded by faecal diversion via a colostomy (Ching and Stahlgreen, 1965). It is in these extensive perianal suppuration problems that the condition may be confused with Crohn's disease.

Acknowledgements

We greatly appreciate the help given to us by the Department of Photography and Medical Illustration, Westminster Hospital, London.

We should also like to thank Dr Peter E. Nicholls for his advice on the pathology findings.

NEW
Praxilene
vasoactivator
INJECTABLE
RELIEVES REST PAIN

NEW

for peripheral vascular disorders

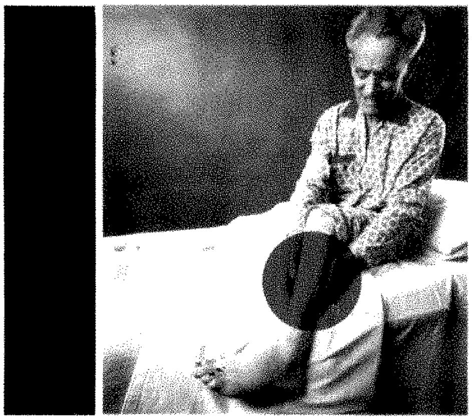
Praxilene

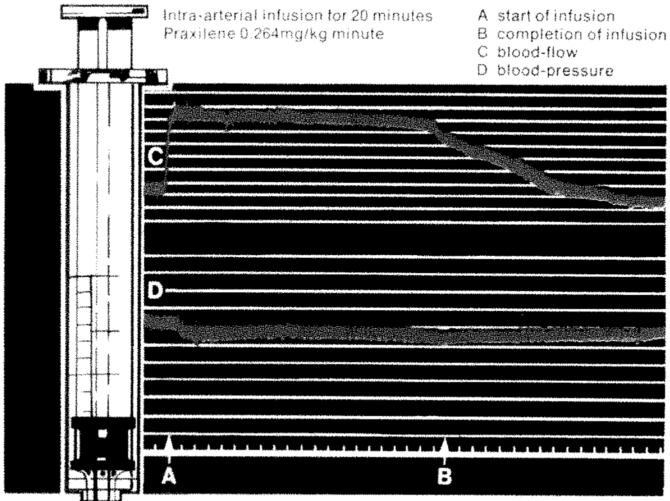
vasoactivator

INJECTABLE

RELIEVES REST PAIN

by flushing out pain producing metabolites
by improving blood-flow – without affecting blood-pressure
by a unique metabolic activity





Fast relief
Praxilene administered parenterally (Intra-arterial; Intravenous; Intramuscular) can give relief of pain within as short a time as one week, in many cases.

Prolonged relief
Relief of pain is prolonged: at the same time the collateral circulation is given the opportunity to develop, resulting in an improved blood supply to the affected limb.

Praxilene has produced excellent results because it has a very wide safety margin and the dosage can be individually tailored to the severity of the disorder.

Praxilene: Unique Vasoactivator

Praxilene: Naftidrofuryl: available as 40mg ampoules and 100mg capsules.

Full prescribing information and dosage schedule on request

Bilateral extradural haematomas

M. V. SUBRAHMANIAN, G. B. RAJENDRAPRASAD AND B. DIBBALA RAO[*]

SUMMARY

Eleven cases of bilateral extradural haematomas were encountered in a total of 49 cases of extradural haematoma during a period of 4 years among 1000 consecutive cases of acute head injury. Assault was held responsible for 60 per cent of the total head injuries. Most of the patients were seen late; 8 were already unconscious and 5 had dilated fixed pupils. All 11 patients died, 4 soon after admission. Nine cases were found to have associated brain damage at autopsy. In 2 cases bilateral extradural haematomas with compression of the brain were the only intracranial abnormalities. In 4 cases a clot was missed on conventional exploration.

BILATERAL extradural haematomas are rare. The previously reported cases are tabulated in *Table I.*

Table I: NUMBER OF CASES OF EXTRADURAL HAEMATOMA REPORTED IN THE LITERATURE

Patients

Among 1000 consecutive cases of acute head injury admitted to the Government General Hospital, Guntur, from February 1970 to January 1974, 49 cases of extradural haematoma were encountered either at surgery or at post-mortem examination. Of these, 11 cases were bilateral.

It is our practice to admit all cases of acute head injury under the care of general surgeons whence they can later be referred to the neurological department if necessary. This may involve avoidable delay in an emergency neurosurgical intervention.

We have analysed these 11 cases of bilateral extradural haematomas regarding their cause, clinical manifestations and radiological features in relation to the operative and autopsy findings.

Cause of head injury

Assault was the main cause of head injury in 7 out of 11 cases. Two patients fell from a moving vehicle, another fell 20 feet from a tree and in one case the nature of the accident was not documented. It is obvious from *Table II* that 60 per cent of the head injuries were the result of assault, which probably accounts for the high incidence of extradural haematoma in this region. Sticks, iron rods and axes were used for assault. In the series reported by Cabraal and Weinman (1964) of 53 cases of extradural haematoma, assault was the main cause in 43·4 per cent.

All our patients were males aged between 12 and 60 years. Nine of them were over 25 years of age. The 2 younger patients (*Cases* 8 and 9) sustained head injuries by falling from moving vehicles.

All the patients were admitted to hospital 4–44 hours after sustaining the injury, and their survival ranged from a few minutes to 8 days.

Clinical features (*Table IV*)

Eight patients were unconscious, 2 were semiconscious and one was conscious. Signs of localization by way of aphasia and hemiparesis were noted in 3 cases. No lucid interval was found in any case.

Radiological features

Plain X-rays of the head were taken in 9 patients, of whom 5 had fractures on both sides of the skull. In 3 cases unilateral fractures were found of which one was a depressed fracture. In *Case* 6 no obvious fracture was noticed on radiological examination but prominent venous channels were present, and a linear fracture in the frontal bone was found at autopsy.

Operative findings

The operative and autopsy findings are given in *Table III.* Seven patients were operated upon. In 3 cases it was possible to evacuate the extradural clots on both sides. In *Case* 1 biparietal craniectomy was done, a parietal extradural haematoma was removed and an associated left-sided subdural haematoma was drained, yet the parieto-occipital extension of the extradural haematoma was missed. In *Case* 2 bilateral extradural clots were evacuated; the brain was markedly compressed and the patient died 11 hours after surgery. The parieto-temporal extension was missed. In *Case* 7 a left parietal extradural haematoma was evacuated and on the right side only a small parietal clot was found. The brain did not expand. A parasagittal haematoma was missed. This patient had

Laceration, 3 × 1 × 1 cm, of the left temporal lobe and base of the frontal lobe 3. Fractures of right parieto-temporal, left parietal and occipital bones. Faciomaxillary fractures on the left side
4	Conventional exploratory burr holes; depressed fracture removed. Laceration of the brain on left parietal lobe noticed	Left fronto-parieto-temporal haematoma of 14 × 7 × 2 cm Right parietal haematoma of 9 × 6 × 2 cm	1. Laceration of left parietal lobe 2. Intracerebral haematoma of left parietal lobe
5	Left parietal craniectomy and evacuation of clot; left subdural haematoma drained. Right temporal burr hole revealed no clot	Left parieto-temporal clot of 9 × 6 × 1 cm Right parietal haematoma of 8 × 6 × 1·5 cm	1. Laceration of the left temporal lobe 2. Laceration of the right frontal lobe 3. Coronal suture diastasis
6	Not operated	Left fronto-temporal clot of 20 × 16 × 8 cm Right temporo-parietal clot 9 × 7 × 6 cm	1. Linear fissured fracture of frontal bone 2. Brain markedly compressed
7	Left temporal craniectomy and evacuation of the clot; small right temporal clot present. Brain did not expand	Parasagittal extradural haematoma of 13 × 12 × 1 cm	1. Laceration, 4 × 3 × 1 cm, of left temporal lobe 2. Brain compressed 3. Sagittal suture diastasis 4. Fracture of both temporal bones
8	Not operated	Left parietal clot of 9 × 8 × 2 cm Right parietal clot of 8 × 6 × 2 cm	1. Extensive scalp haematoma 2. Bifrontal subdural haematoma of 5 × 4 × 2 cm 3. Fracture of occipito-temporal bones of both sides 4. Fracture of base of middle cranial fossa
9	Bilateral exploratory burr holes; depressed fracture removed	Extensive extradural haematomas occupying both sides	1. Extensive scalp haematoma 2. Contusion of corpus callosum and midbrain 3. Brain compressed 4. Fracture of frontal bone extending to both temporoparietal bones
10	Not operated	Extensive extradural haematomas occupying entire extradural space on both sides	1. Subdural haematoma of 150 ml in right frontal region 2. Fracture of frontal bone extending to orbit
11	Bilateral exploratory anterior burr holes	Left pre-frontal extradural haematoma of 6 × 3 × 1 cm Bilateral posterior fossa extradural haematomas	1. Laceration of left frontal lobe 2. Fracture of left frontal bone 3. Fracture of anterior cranial fossa

survived the longest when death occurred 8 days after the injury.

In 4 patients explored by means of conventional burr holes the clots were missed. In 2 of these cases depressed fractures were removed and brain lacerations were found. In *Case* 11 a posterior fossa extradural haematoma was missed as only exploratory burr holes were made because the patient was conscious and aphasic.

Four cases died before any operative intervention, i.e. within a short time of admission.

Autopsy findings

All the cases were submitted to autopsy for forensic reasons. Extensive bilateral extradural haematomas of varying sizes were encountered in association with severe damage to the brain. In most cases the haematomas were parieto-temporal, 2 cases were parasagittal and in 2 cases the collections were diffuse (*Table V*), occupying the entire extradural space on both sides (*Cases* 9, 10). In *Case* 11 left frontal injury with fracture was associated with a left-sided pre-frontal extradural haematoma and a bilateral posterior fossa extradural haemorrhage (*Table III*).

Laceration of the brain was found in 6 cases, subdural haematoma in 4 cases and intracerebral haematoma in 1 case. Pontine haemorrhage in 1 case and contusion of the corpus callosum and the brainstem in another were also found.

Fracture of the skull bones was detected in all the cases during the autopsy examination. Five of these extended to the base of the skull and one fracture was depressed.

Mortality

All the patients in this series died, 4 within a short time of admission and before any neurosurgical intervention. Nine patients had severe associated brain damage. Of the 7 operated cases, 5 had laceration of the brain and in 1 case contusion of the corpus callosum and midbrain. Two patients (*Cases* 2 and 6) who had brain damage other than that due to the bilateral extradural haematomas could have been saved by early operation.

Case 11 was an unusual presentation of bilateral posterior fossa extradural clot where the patient remained conscious and the only clinical feature was aphasia. He was also found to have a pre-frontal extradural clot.

Discussion

Forty-nine cases of extradural haematoma in 1000 patients with head injuries is a high incidence, as is shown in *Table I*. Moreover, 11 cases of bilateral extradural haematomas amount to 22·4 per cent of the total extradural haematomas and 1·1 per cent of the total head injuries.

Assault was responsible for 60 per cent of the head injury cases and 7 out of the 11 bilateral extradural haematomas. In the 53 cases of extradural haematoma reported by Cabraal and Weinman (1964) assault was the main cause in 43·4 per cent.

Table IV: MAIN CLINICAL FEATURES

Clinical feature	No. of cases
Level of consciousness at time of admission:	
Unconscious	8
Semiconscious	2
Conscious	1
Aphasia	3
Hemiparesis	2
Decerebrate response	2
Generalized convulsions	1
Pupillary changes	
Dilated and fixed	5
Paradoxical reaction to light	1
Not significant	5

Table V: SITES OF BILATERAL EXTRADURAL HAEMATOMAS

Site	No. of cases	
	Right	Left
Parietal	3	2
Parieto-temporo-occipital	2	1
Parieto-temporo-frontal	—	2
Parieto-temporal	1	1
Temporal	1	1
Parasagittal	1	1
Diffuse	2	2
Frontal	—	1
Posterior fossa	1	

We may ask ourselves:

1. Why is the incidence of extradural haematoma so high? The only striking factor on reviewing the causes is that assault was responsible for 60 per cent of the cases (*Table II*).

In the series of Dayananda Rao et al. (1967), where also the majority of the cases who died were submitted for post-mortem examination, only 1 case of bilateral extradural haematoma was found out of 4500 cases of head injuries during a period of 6 years.

The age grouping reveals that the incidence is highest in those over 25 years of age. In this connection it is worth noting that the injuries were mostly sustained in 'faction' fights with a view to kill, which may explain the seriousness of the intracranial damage that was found.

2. What lessons may be learnt? In every case of assault the possibility of bilateral extradural haematoma must be borne in mind. In 2 cases extradural haematomas alone were found at post-mortem examination. These cases could have been saved by timely and proper intervention. Although the remaining 9 cases had associated brain damage, evacuation of the clot before the development of irreversible changes could have considerably reduced the mortality.

Routine X-rays failed to reveal the presence of a linear fracture in one case and a depressed fracture in another. At post-mortem all the cases showed evidence of multiple fractures.

The ancillary methods of investigation such as angiography have yet to establish their usefulness in the care of emergency cases in this unit.

Using two conventional burr holes in such serious cases the chances of missing the lesions are great. It is therefore advisable to make at least four exploratory burr holes. The only patient who had a supratentorial frontal extradural haematoma and a posterior fossa clot was clinically conscious and neurologically normal except for aphasia. Conventional burr holes failed to reveal the frontal extradural haematoma. Probably the extent of the posterior fossa clot was not sufficient to cause changes in the vital functions.

Acknowledgements

We are grateful to the Department of Forensic Medicine, Government General Hospital, Guntur, for the details of the post-mortem findings.

We also wish to thank the Superintendent, Government General Hospital, Guntur, for permission to publish this article.

Injury of the facial nerve during surgery of the parotid gland

C. M. WARD*

SUMMARY

The notes of 158 patients who had undergone surgery of the parotid gland for benign and malignant disease were studied to discover the circumstances in which the facial nerve might be injured.

Limited surgery carried as great a risk of injury to the facial nerve as during extended surgery. Extended surgery provided greater risk of injury to the facial nerve on secondary exploration (71 per cent) than on primary exploration (6·5 per cent).

It is concluded that every primary exploratory procedure of the parotid gland should be a formal conservative parotidectomy unless the tumour is obviously malignant.

THE principle of surgery of the parotid gland is adequate removal of the tumour with functional and anatomical preservation of all branches of the facial nerve whenever possible. This principle has been emphasized and re-emphasized since surgery of the parotid gland became a reasonable proposition, yet little is written of the incidence of injury to the facial nerve. This paper reviews the results of operations on the parotid gland noting the circumstances of injury to the facial nerve.

Patients and methods

Between 1963 and 1972 158 patients with lesions of the parotid gland were treated surgically by the consultant and junior staff in the Departments of Ear, Nose and Throat Surgery, General Surgery and Plastic Surgery, Frenchay Hospital, Bristol.

The usual classification of peripheral nerve injury, namely neuropraxia, axonotmesis and neurotmesis, is difficult to apply in this study as several of the patients had been referred from counties remote to Frenchay Hospital. These patients were seen in their own district hospitals after a more limited local follow-up than applied to patients referred from the more immediate vicinity of Frenchay Hospital. Therefore, in the context of this retrospective study, injury to the facial nerve is defined as damage to one or more branches leading to unacceptable functional or cosmetic disability that may or may not recover after 6 months following surgery. This definition takes no account of neuropraxia but embraces neurotmesis and axonotmesis without distinguishing between them. The distress of the patient, however, is no less in that time whether the axon or the neuron of the facial nerve has been ruptured.

The operations performed were very variable but basically fall into five groups. These are: enucleation, removal of the tumour with a cuff of normal tissue, removal of the lower pole of the parotid gland, superficial parotidectomy, which may be extended if the tumour is found in the deep lobe, and total parotidectomy with or without deliberate sacrifice of the facial nerve. The first three groups involve procedures in which the trunk of the facial nerve is not identified. The techniques can therefore be classified more simply by: (1) limited surgery, (2) conservative formal parotidectomy and (3) total parotidectomy.

No attempt has been made to differentiate between the types of malignant tumour nor has an attempt been made to study in detail the recurrence of these tumours or pleomorphic adenomas in relation to surgical technique.

Table I: COMPARISON OF THE PRESENT SERIES WITH THAT OF ENEROTH (1966)

	Frenchay Hospital 1963–72 ($n = 158$)		Karolinska Sjukhuset 1950–62 ($n = 802$)
Type of tumour	No.	%	
Benign	126	79·7	83·4
Pleomorphic adenoma	89	56·2	69·0
Adenolymphoma	14	8·8	5·0
Oxyphilic adenoma	1	0·6	1·0
Benign lympho-epithelioma	2	1·3	0·8
Mesenchymal tumours	2	1·3	1·5
Pseudotumours	18	11·4	6·1
Malignant	32	20·3	16·6

Table II: INJURY TO THE FACIAL NERVE DURING SURGERY OF PLEOMORPHIC ADENOMAS

Treatment	No. of cases	Injury to facial nerve
Limited surgery	22	0
Limited surgery after previous surgery	2	1
Conservative formal parotidectomy	52	0
Conservative formal parotidectomy after previous surgery	13	9
Total parotidectomy	2	0
Total	91	10

Results

Thirty-two patients (20·3 per cent) had malignant disease of the parotid gland while 126 (79·7 per cent) had benign lesions. The main difference in these figures from those of the Karolinska Sjukhuset (Eneroth, 1966) is the lower proportion of pleomorphic adenomas and the higher proportion of pseudotumours (*Table I*).

* Department of Plastic Surgery, Frenchay Hospital, Bristol. Present address: Wessex Centre for Plastic and Maxillofacial Surgery, Odstock Hospital, Salisbury.

Injury to the facial nerve during surgery of the pleomorphic adenomas is shown in *Table II* and during surgery of other benign lesions in *Table III*. In *Table IV* it is very apparent that previous surgery of the parotid gland for benign disease leads to a greater risk of injury to the facial nerve on subsequent exploration regardless of the surgical procedure adopted.

The results of surgery of malignant tumours of the parotid gland in *Table V* show that of 13 patients without previous treatment, 2 had facial nerve injuries, whereas of 4 patients previously treated, 3 had nerve injuries at subsequent operations.

Considering all the patients in whom attempts were made to preserve the facial nerve, 8 out of 124 (6·5 per cent) had facial nerve injuries from primary surgery while 15 out of 21 (71 per cent) had facial nerve injuries from secondary surgery.

Discussion

It is difficult to compare results of surgery on the parotid gland. The reports differ greatly from an individual who takes a particular interest in the treatment of disease of the parotid gland and who would therefore have better results than those of a group of surgeons of variable experience for whom surgery of the parotid gland is not necessarily a special interest. Furthermore, the definition of injury to the facial nerve differs according to the duration of follow-up of the patient and to the grade of paralysis, which is a subjective observation. Thus, of a personal series of 105 patients with pleomorphic adenomas treated by total conservative parotidectomy (Kidd, 1969), there were no permanent paralyses except where a branch of the nerve was deliberately sacrificed, while for a group of surgeons (Gore et al., 1964) 7 out of 35 patients developed facial paresis lasting more than 3 months from surgical techniques varying from limited to more extensive procedures.

In a detailed analysis of functional paralysis of the facial nerve following parotidectomy (Patey and Moffat, 1961) the paralyses were graded into three groups of which grade III failed to improve until 2–6 months after operation. Of 31 patients primarily treated by total conservative parotidectomy, 9 (29 per cent) developed grade III paresis, while of 64 patients treated by superficial parotidectomy, 4 (6 per cent) developed the same degree of facial weakness.

Limited surgery such as enucleation may occasionally be considered as a safer procedure or even the treatment of choice for a benign parotid tumour (Guras et al., 1973), yet in this series (*Table IV*) 3 out of 40 benign lesions treated primarily by limited procedures developed facial paresis compared with 2 out of 67 benign lesions treated primarily by conservative formal parotidectomy. It therefore appears that the facial nerve and its branches are as much at risk during limited surgery as during extended surgery. No matter how limited might be the surgical procedure adopted during exploration of a parotid tumour, every branch must be carefully identified and preserved.

Table III: INJURY TO THE FACIAL NERVE DURING SURGERY OF BENIGN LESIONS

Type of tumour	Treatment	No. of cases	Injury to facial nerve
Adenolymphoma	Limited surgery	10	2
	Limited surgery after radiotherapy	1	1
	Conservative formal parotidectomy	3	0
Oxyphilic adenoma	Limited surgery	1	0
Benign lympho-epithelioma	Limited surgery	1	1
	Conservative formal parotidectomy	1	0
Mesenchymal tumours			
Lipoma	Conservative formal paratidectomy	1	1
Lymphohaem-angioma	Conservative formal paratidectomy after previous surgery	1	1
Sialectases	Limited surgery	2	0
	Conservative formal parotidectomy	5	0
	Total parotidectomy	2	1
Cysts	Limited surgery	3	0
	Conservative formal parotidectomy	4	1
Calculi	Limited surgery	1	0
	Conservative formal parotidectomy	1	0
	Total	37	8

Table IV: INJURY TO THE FACIAL NERVE DURING SURGERY OF ALL BENIGN LESIONS

Treatment	No. of cases	Injury to facial nerve
Limited surgery	40	3
Limited surgery after previous surgery	3	2
Conservative formal parotidectomy	67	2
Conservative formal parotidectomy after previous surgery	14	10
Total parotidectomy	4	1

Table V: INJURY TO THE FACIAL NERVE DURING SURGERY OF MALIGNANT TUMOURS

Treatment	No. of cases	Injury to facial nerve
Limited surgery	3	0
Conservative formal parotidectomy	6	0
Conservative formal parotidectomy after previous surgery	2	1
Total parotidectomy with attempts to preserve the facial nerve in 4 cases	15*	2
Total parotidectomy after previous surgery with attempts to preserve the facial nerve in 2 cases	3†	2

* Eight patients had preoperative paresis.
† One patient had preoperative paresis.
Radiotherapy was given to 2 patients with anaplastic carcinoma and to 1 patient with adenocarcinoma who refused an operation.

It is known that there is a significant recurrence of pleomorphic adenomas after limited surgery (Leading Article, 1972; Hugo et al., 1973). In the present series (*Table II*) 9 out of 13 patients with pleomorphic adenoma treated secondarily by conservative formal parotidectomy had injuries of the facial nerve. Of a personal series of 100 patients with pleomorphic adenoma treated by superficial parotidectomy (Eddey, 1970), 15 had had previous limited surgery of which

20 per cent developed permanent facial paralysis. Therefore it becomes apparent that a benign tumour of the parotid gland should be treated by extended surgery not only to reduce any chance of recurrence but also to prevent risk of injury to the facial nerve that is more likely during reoperation for a recurrence after limited surgery.
